While the pathological relation between uric acid and gout is acknowledged by most authorities, there are some who altogether dispute the connection, and maintain that this acid is an inert innocuous substance. One view which has been advocated during recent years demands special notice, namely, that which refers gouty phenomena to the effects of the alloxur-bases (xanthin, hypoxanthin, &c.) which are regarded as the *materia peccans*. Experiments have been made which are said to show the injurious effect of these bases on the kidneys. Alloxuric substances (uric acid and bases) are believed by many, adopting the theory of Horbaczewsky, to be derived from nuclein, being the ultimate products of the breaking down of the material in the body which is contained in tissues and cells, and probably mainly from that in leucocytes. According to Kolisch, as long as the uric-acid-forming organs are intact, especially the kidneys, the bulk of the products of nuclein-metabolism are excreted as uric acid. If these organs are diseased less acid is formed, and there is a corresponding increase in the production of xanthin-bases. He believes that in gout a constitutional tendency to the breaking down of the nuclein is inherited, but it is only when the renal functions become impaired from any cause that grave manifestations of the diathesis make their appearance. Croftan is of opinion that normally all the nuclein is converted into uric acid, which is innocuous and non-toxic, and that a perversion of the normal function leads to the formation of alloxur-bases, which are toxic. He considers that in a uratic subject there is a tendency to disintegrate a quantity of nuclein far in excess of the quantity normally disintegrated—in short, that nuclein-metabolism is excessive.

With regard to the local manifestations of gout, the joints on which most stress falls are generally affected first. Indeed, as already stated, Ebstein maintains that a nutritive disturbance of the affected tissue is the primary change, leading ultimately to its necrosis, and that uratic crystallisation is secondary, not occurring before complete death of the damaged texture. He looks upon sodium urate as a directly poisonous irritant wherever deposited, the injurious effects varying according to the quantity and concentration of the deposit, and the vulnerability of the special tissue involved, firm textures resisting better than those of looser character.

Klemperer considers that the deposition of urates in the tissues is due to a special chemical affinity of necrotic areas for uric acid, the necrosis being due to an unknown cause. Mordhorst, in discussing the deposition of urates in the tissues of gouty patients, dissents entirely from Ebstein's view. He states that in a saturated solution a urate is thrown down in the form of minute spherules which grow by accretion. He holds that under unfavourable conditions the fluids of the tissues liable to gouty inflammation may become neutral or even acid in reaction, and the granular urate, which is always first deposited, or even sodium biurate itself, may consequently undergo decomposition with the formation of crystals of free uric acid, which may block even the larger lymphatics of the part, and so set up an acute gouty inflammation. Since, however, the acidity of the affected tissues can only be temporary, the free uric acid will be reconverted into granular urate when alkalinity is restored, and ultimately into sodium biurate. According to this view the inflammatory process may be regarded as

curative, since it causes an increased flow of alkaline blood through the part, and encourages osmotic interchange between the focus of inflammation and the neighbouring capillaries.

While acute articular gout is almost invariably regarded as inflammatory, George Balfour has advanced an altogether different view, and affirms that from beginning to end of a gouty paroxysm there is neither sign nor symptom of inflammation. He maintains that its phenomena are readily and only explicable on the supposition of a stasis (or block) in the capillaries of the affected joint. This is accompanied by the formation of an anæmic area in and around the joint, and naturally the veins connected with this area of negative pressure get filled by reflux from the contiguous valveless veins. Plasma slowly accumulates within this area, the corpuscular elements also escape by diapedesis into the tissue-interspaces, and the red corpuscles readily part with their colouring matter. The blood-plasma contains urates, which are not very soluble, and when it accumulates within the anæmic area surrounding a gouty joint, the salts slowly crystallise out and get left behind when the serous part of the fluid is reabsorbed. Another view which has been brought forward as to the nature of an acute attack of gout is that the inflammation is not in the articulation at all, but that there is a neuritis in the surrounding tissues.

ANATOMICAL CHARACTERS.—The results of *post-mortem* examinations show that even in the very earliest period a deposit of urates takes place in the tissues of the joint; and as the attacks are repeated again and again, the deposit increases, until at last it may form considerable masses, and infiltrate extensively all the structures entering into the formation of the joint. The articulation then becomes permanently enlarged and distorted, while the ligaments are thickened and more or less stiff or even quite rigid, until ultimately complete ankylosis may be produced. The deposit seems to commence in the substance of the cartilage covering the ends of the bones, starting near its superficial or free surface, and gradually extending more deeply, though for a time a thin layer of cartilage lies between it and the cavity of the joint. This deposit at first forms a whitish opacity, but as it becomes more abundant it encrusts the cartilages, and also the inner surface of the ligaments, and the surfaces of fibro-cartilages where these exist. More or less extensive spots or patches become in time distinctly visible, and even the entire surfaces of the bones forming a joint may be covered with a chalky-looking substance. 'The appearance of articular cartilage in which simple deposit of urates has taken place exactly resembles that which would result from smearing or splashing the surface with fresh white paint' (Duckworth). The synovial membrane may also present white points, but the synovial fringes at their margins seem to escape, on account of their vascularity. In the larger articulations synovial fluid may be thickened, and may even contain separate crystals or tufts of the urate. Subsequently the ligaments and adjoining structures are infiltrated, and it is to this cause that the stiffness or rigidity of gouty joints is mainly due. Distinct masses of deposit may, however, form, which also interfere with movement. They are known as *tophi* or *chalk-stones*. In course of time the tissues covering a gouty joint may be destroyed, including the skin, the chalky-looking substance

being thus exposed, and unhealthy suppuration and ulceration set up, or even gangrene. Very rarely suppuration takes place in a gouty joint itself, or hæmorrhage may occur.

The opaque white substance characteristic of articular gout consists of fine crystals, in the form of needles or prisms. They are chiefly arranged in minute clusters, radiating from a centre; and in the cartilages they form a more or less compact network. Chemical examination shows that they are chiefly composed of biurate of sodium.

The metatarso-phalangeal articulation of the great toe is the one primarily attacked in the large majority of cases of gout; and this joint, on one or both sides, may alone present any change. As usually seen, however, the disease has progressively involved many joints. In the feet it may implicate all the articulations, but it is a curious fact that the tarso-metatarsal and the phalangeal joints of the great toe generally escape, or are but little affected. Similarly, all the joints of the hands and fingers are often involved, but the metacarpo-phalangeal joint of the forefinger is one of the most commonly attacked. The gouty change not uncommonly extends to the larger joints, more especially those of the leg, but the shoulder and hip-joints are very rarely implicated. In exceptional cases other articulations are found involved, such as the temporo-maxillary, those of the spinal column, of the pelvis, or even of the larynx in rare instances. According to some writers fibrillation and erosion of the cartilages take place before the biurate of sodium is deposited.

Coming now to other structures, deposits of urate may occur in various parts of the body, sometimes abundant and widely spread, in connection with bursæ, tendons and aponeuroses, sheaths or the substance of muscles, the sclerotic coat of the eye, the cartilages of the external ear, eyelids, nose, or larynx, under the skin, or rarely in the cerebral and spinal meninges. Urates have also been found in concretions on the aortic and mitral valves, and in plates upon the arch of the aorta. More or less serous effusion may be present in bursæ which are the seat of uratic deposits. The exact composition of these tophi varies, and they may contain calcium urate, oxalate, or phosphate, as well as sodium chloride and organic matter, in addition to sodium urate.

As regards bone, the periosteum is often affected, and some writers have described a deposit of urate in bone itself; but Garrod has not found evidence of its having originated in this tissue. He considers that the periosteal formations sometimes acquire sufficient size to press on the osseous tissue, and to cause its absorption.

The *kidneys* may be affected at a very early period, even when there have been little or no external manifestations of the complaint. In the first instance a deposit of sodium bi-urate takes place, probably within the renal tubuli, which afterwards involves their walls and penetrates to the intertubular tissue. This is seen in the form of white streaks in the course of the tubuli, and of white points at the extremities of the papillæ. The deposit goes on increasing, and a chronic inflammatory process is set up, ending ultimately in the production of a variety of 'granular contracted kidney,' known as the 'gouty kidney' (see KIDNEY, Diseases of). Other morbid states in connection with the urinary organs observed in some cases of

gout are the presence of gravel or calculi consisting of uric acid, urates, or oxalate of calcium; pyelitis; chronic cystitis; and urethritis.

In the course of gout other morbid changes often arise. Among these are: changes in the pharyngeal structures; congestion, catarrh, or more serious inflammation of some part of the alimentary canal; affections of the teeth; congestion or catarrh of the air-passages, chronic bronchitis, or dry bronchial catarrh, emphysema, and, some think, pneumonia; congestion of the liver, fatty disease, perhaps cirrhosis, and gall-stones; meningitis, neuritis, perineuritis, cerebral hæmorrhage; cardiac changes, including chronic valvulitis and degeneration of the valves, and hypertrophy, followed by degeneration of the cardiac walls, or primary degeneration associated with disease of the coronary arteries; atheromatous changes in the vessels, hypertrophy of the muscular coat of the small arteries, or arterio-capillary fibrosis; various diseases of the skin, such as erythema, urticaria, eczema, psoriasis, a peculiar macular eruption, as well as changes in the nails; iritis, hæmorrhagic retinitis, and other conditions of the eyes; and affections of the ear. How far some of these conditions can be directly attributed to the gouty diathesis, or are merely the result of the same causes which have induced this diathesis, may be fairly disputed. It is worthy of remark that acute inflammation in connection with the heart is not met with in cases of gout, and this has been attributed to the great vascularity of the cardiac tissues.

The principal change in the blood is the excess of uric acid, which can be found especially during the acute paroxysms. The other changes are unimportant. See BLOOD, Morbid Conditions of.

Uric acid has been obtained from the fluid contained in the blebs produced by blisters; from inflammatory serous effusions; from synovial fluid; from dropsical accumulations, such as ascites; and from the subarachnoid fluid.

CLINICAL HISTORY AND SYMPTOMS. — The clinical history of gout is a very varied one, and the symptoms observed in different cases which are regarded as of a gouty nature are exceedingly numerous and diverse. The custom of looking upon every acute illness, particularly inflammation of organs, occurring in gouty subjects, as being due to the gouty condition is unjustifiable, though it may be acknowledged that gout does often modify their clinical history.

1. Premonitory Symptoms. — Suspicious twinges or uncomfortable sensations about the toes or fingers are commonly noticed from time to time before the first actual fit of gout occurs. In a large number of cases, however, no definite premonitory symptoms immediately precede the first gouty paroxysm; but in connection with subsequent paroxysms prodromata are usually marked, so that confirmed gouty patients can predict when an attack is imminent. The most obvious of these are digestive and hepatic disorders, attended with abundant flatulence and eructations, heartburn, acidity, and constipation or diarrhœa, with unhealthy stools, the tongue being often large, flabby, and much furred; palpitation or uncomfortable sensations about the heart; catarrh of the throat and respiratory passages, tonsillitis, violent fits of sneezing, or asthmatic attacks; derangements of the nervous and muscular systems, indicated by a liability to headache, giddiness, attacks of megrim, noises in

the ears, disorders of vision, irritability of temper and fretfulness or lowness of spirits, languor, impairment of mental vigour and intellectual hebetude, heaviness or drowsiness, sleep, however, being restless, disturbed, and attended with unpleasant dreams, peculiar grinding of the teeth, sometimes associated with somnambulism, numbness or tingling in the limbs, especially in the fingers or toes, neuralgia or neuritis in various parts, twitchings, startings in the limbs, muscular cramps, especially in the calves of the legs, or possibly even convulsions, lumbago and other forms of muscular rheumatism; profuse perspirations; certain skin-affections; and changes in the urine. This excretion usually tends to become high-coloured and deficient in quantity, and to deposit urates abundantly, or even crystals of uric acid. In advanced cases of gout, however, the urine may be pale, watery, and clear immediately before an acute attack supervenes. Some patients are warned of the approach of a gouty fit by feeling unusually well, both physically and mentally.

2. Acute Articular Gout. — The first acute fit of gout comes on as a rule during the night, usually between 2 and 5 A.M. The patient is aroused from sleep by uneasiness or pain, generally referred to the ball of the great toe on one side, and the joint is found to be inflamed, the inflammation increasing in intensity, until it usually becomes extremely severe. In some instances the corresponding joints on both sides are attacked simultaneously, in rapid succession, or alternately. It must not be forgotten that gout may start in any of the smaller joints of the foot or hand, or even in the middle-sized joints, especially the knee or ankle. It has been affirmed that, next to the great toe, the metacarpo-phalangeal joint of the index-finger is most liable to be first attacked. Exceptional cases have come under the writer's notice, in which the disease implicated several joints at a very early period of its course, the feet, however, being free.

Severity of the pain is certainly a striking feature in the majority of cases of acute gout, especially in early attacks. Directly the foot is affected, any attempt to stand causes much suffering, and the pain speedily increases, until it becomes very intense, or almost unbearable. It is described in different cases as burning, throbbing, aching, tearing, plunging, boring, or piercing. The pain prevents sleep during the night, but towards morning it tends to diminish, and during the day there is usually comparative ease, an exacerbation again taking place as evening approaches, which goes on increasing towards night. Tenderness is very marked, and is often so exquisite that the patient dreads to be touched, and cannot bear the least movement or jarring of the affected part, or sometimes even the weight of the bedclothes, or the slightest shaking of the room. The objective signs of inflammation in connection with a gouty joint also soon become very prominent as a rule.

These are marked redness, which may be very deep and sometimes tends to duskiness or lividity, while the veins are enlarged and turgid; considerable local heat, as revealed to the touch and the clinical thermometer; and much swelling, the skin covering the part assuming a tense and shining appearance. When several joints in the foot or hand are affected, diffused redness and swelling are noticed. The tumefaction is due to effusion not

only into the interior of the articulation, but also into the surrounding tissues, subcutaneous oedema being a marked feature in connection with gouty inflammation. This can be better appreciated when the acute symptoms subside, so that pressure can be borne, which shows the pitting characteristic of oedema, and this may hold on for some time. However intense the objective signs of inflammation may be, it is an extremely rare event for acute gout to end in suppuration. As they subside, marked desquamation of the skin usually takes place. As the swelling increases, the subjective sensations generally diminish in severity; but during the progress towards recovery, intense itching is apt to supervene.

An acute attack of gout is almost always attended with more or less *general* symptoms; but it is an important fact that their severity depends upon the extent and intensity of the local manifestations of the disease, and upon the accompanying symptoms. Chills or even actual rigors may be felt at the outset, followed by febrile phenomena, sometimes slight, in other cases marked, the pyrexia being as a rule strictly secondary or symptomatic. The skin feels hot, and usually perspires, but not profusely; the temperature is moderately raised, presenting no definite variations, though marked remissions are generally observed towards morning; the pulse is increased in frequency; and the digestive organs are much disordered, as evidenced by anorexia, thirst, thickly furred tongue, offensive breath, and constipation. The urine is generally deficient in quantity, and may be very scanty, high-coloured, and concentrated; its acidity is increased; and on standing, an abundant deposit of amorphous urates often forms, varying in colour according to circumstances, being pale-buff, yellowish-red, dark or brick-red, or intense pink if the fever is high. According to the most recent researches the excretion of uric acid is increased during the course of an attack of acute gout, especially towards its close; and there is also said to be an excess of the alloxur-bases. The patient is usually exceedingly restless, and cannot lie with comfort in any position; sleep is much disturbed or altogether prevented; and cramps of the calves of the legs or of other muscles may still further aggravate the suffering. All these symptoms tend to increase the constitutional disorder. The temper is generally very irritable, and may even be violent.

The duration of the first fit of gout varies. It usually ranges from four or five days to a week or ten days, but may last two or three weeks or more, there being then commonly intermissions or remissions, and several joints being involved in succession. The termination of the gouty paroxysm may be attended with critical phenomena, such as free perspiration, diarrhoea, or a very abundant discharge of urates. After the attack the patient may not recover his previous health for some time; but not uncommonly he feels better than before. As a rule, the affected joints are apparently quite restored after early attacks of gout; but more or less stiffness or even deformity may remain. Oedema may also persist for a considerable time, especially if the inflammatory condition has been prolonged.

One of the characteristic features of gout is the tendency which the paroxysms exhibit to recurrence with increasing frequency. In not a few instances the second fit does not occur until an interval of two or three years or more has elapsed, but in most this is not prolonged beyond a year. The same interval

may be noticed between the next few paroxysms, but as the disease progresses they return twice a year, then more frequently, and at last become more or less constant. At the same time the mischief extends as regards the joints. It may be limited to the great toe for some time, but in successive fits spreads to the other articulations of the foot, to the hands, the ankles and knees, the wrists and elbows, very rarely to the hips and shoulders. In short, gout tends in time to involve nearly all the joints indiscriminately, and several may be implicated during a fit. Moreover, those articulations which are repeatedly attacked become more and more disabled and deformed. The symptoms in connection with a particular joint tend to diminish in intensity the more often it is affected. As additional articulations become involved, however, the general symptoms often increase in severity, and the patient does not recover in the intervals. The duration of the attacks becomes longer as their frequency increases. The rapidity of the progress of gout is very different in different cases; and the time taken to produce permanent mischief in the joints varies considerably.

In feeble persons the subjective and objective symptoms of a gouty paroxysm may be comparatively slight, but the ultimate effects upon the joints are often much worse. In some instances articular gout develops very insidiously, without any acute attacks. The pain in connection with a particular joint depends considerably on its structure, being usually much more marked if its ligaments, or the parts around, are rigid and unyielding. Previous injury or disease affecting a joint may likewise modify the symptoms.

3. **Chronic Articular Gout.**—In course of time more and more of the joints become permanently and obviously affected, a condition of chronic articular gout being established. The permanent changes are indicated by the articulations becoming enlarged, deformed, and irregular in shape, often presenting nodulations or bulgings, which may attain a large size. They are also stiff and crippled in their movements, at last becoming quite immovable and rigid; and being either permanently flexed, extended, or sometimes even bent backwards. The interference with movement and the deformity do not bear any necessary proportion to each other, the one or the other predominating according to the mode in which the uratic deposit has taken place. The more this infiltrates the ligaments and surrounding tendons, the greater becomes the impediment to movement. The fingers are particularly liable to be much altered in chronic gout. Tophaceous nodules are often formed in connection with the joints known as 'Heberden's nodes.' A common condition is said to be stiff flexion of the metacarpo-phalangeal and second phalangeal joints of a finger, with over-extension of the first phalangeal joint, so that its knuckle presents a deep hollow. Deflexion of the fingers to the ulnar side of the fore-arm is observed in some gouty cases. The toes are also sometimes distorted towards the outer side of the foot.

Gouty concretions in connection with joints, by their mere mechanical and irritative effects, are liable to cause damage to the adjoining structures. They may be seen stretching or shining through the skin, and causing it to assume a bloodless appearance, or, on the other hand, rendering it congested and bluish, the veins also being enlarged. Ulti-

mately the entrance of pyogenic cocci may produce an abscess around a concretion ; or more frequently the skin may merely give way from the continued pressure. Thus the so-called *chalk-stones* are exposed, and may come away either in a liquid form or as solid particles or masses ; occasionally there is a free discharge of pus as well. Ulcers are left, of an unhealthy and atonic character, and usually presenting no disposition to heal. There may be a number of these ulcers in the same individual, on the hands and feet.

When bursæ are involved, much deformity is produced. They are easily felt, usually presenting a combination of hardness and fluctuation, due to the presence of both concretions and fluid in the bursal cavity. These signs are chiefly noticed in the bursa over the olecranon. Abscesses may also form in connection with these deposits, and the latter may thus be completely got rid of, the abscess subsequently healing rapidly.

In cases of chronic articular gout the general system tends to become permanently affected. The patients are generally more or less feeble ; they may be thin and pale or sallow-looking ; or plethoric, but with flabby tissues, and presenting signs of languid circulation, with enlarged capillaries about the face. They often suffer from disorders of digestion and other symptoms already described ; but not uncommonly, as gout assumes a more chronic form, patients feel better, becoming habituated to their condition. It is remarkable that those suffering from numerous gouty abscesses often exhibit but little constitutional disturbance.

The urine in chronic gout generally becomes abundant, watery and pale, of low specific gravity, and deficient in solid ingredients. Very different statements are made as to the amount of uric acid and alloxur-bases discharged. Some writers affirm that they are increased ; others that they are diminished ; and still others that there is no constant relation, either as regards the total amount, or in the proportion between uric acid and xanthin-bases. This last view is probably correct. Deposits of urates in urine are not often observed in cases of advanced chronic gout, except before an acute exacerbation. Glycosuria is not uncommon in gouty persons, and there may be distinct diabetes mellitus. Oxaluria is also frequent.

4. Irregular Gout.—The clinical phenomena which are recognised as irregular manifestations of gout may assume either an *acute* or *chronic* form. They may be observed in persons who are distinctly subject to articular gout ; or in those in whom the disease is not so obviously revealed. Moreover, their intensity is often in an inverse ratio to that of the joint-affection, and the two classes of symptoms may exhibit a remarkable tendency to alternation, when the articular symptoms are prominent those connected with other parts being slight or absent, and *vice versa*. Acute symptoms are particularly liable to arise when, from any cause, during the progress of a gouty fit the joint-inflammation is checked suddenly or rapidly—*retrocedent gout*. At other times internal symptoms seem to be due to a want of development of the external phenomena—*suppressed gout* ; and when the latter appear, the former subside.

It must suffice to indicate here the general nature of the symptoms of irregular gout. The *acute* symptoms are mainly associated with the digestive apparatus, the circulatory system, the respiratory

organs, or the nervous system. In connection with the *digestive apparatus*, acute dysphagia may occur, attended with spasm of the pharynx and œsophagus. Acute inflammation of the salivary glands is of rare occurrence. The most important symptoms belonging to this group are those due to gastric disturbance. This may be of the nature of severe cramp or gastralgia, characterised by a sudden, intense, spasmodic pain in the epigastrium, relieved by pressure, and accompanied by a sense of great weight and oppression ; the patient presenting an aspect of much suffering, distress, and anxiety ; or being even more or less collapsed and prostrated. In other cases the symptoms are those of acute gastritis, bilious vomiting being prominent. Intestinal colic, or even muco-enteritis, may also occur in connection with gout. Hepatic disorder is common. The *circulatory system* is not uncommonly implicated. The heart is liable to be disturbed in its action during the attacks of gastralgia, but this disturbance may also be observed independently. There may be severe palpitation, the action of the heart being very rapid, irregular, or even intermittent, accompanied by most unpleasant sensations over the cardiac region, præcordial anxiety, often a feeling of oppression or constriction, dyspnoea or a sense of suffocation, and much distress, anxiety, and dread of death ; the pulse tends to be weak and small, or may be irregular ; and sometimes the attacks are attended by signs of collapse. In other instances the cardiac disorder is evidenced by very feeble or slow action, with a tendency to syncope. Again, there may be all the phenomena of a severe anginal attack (*see* ANGINA PECTORIS). Sansom, in discussing the effect of influenza on the gouty condition, expresses the opinion that the most important association of the post-influenzal irregular heart is with gout. Irregular gout affecting the *respiratory system* is mainly indicated by asthmatic paroxysms. In some cases there is a marked liability to acute catarrh of the air-passages, and crystals of uric acid have been found in the expectoration. Bronchitis is more obstinate in gouty subjects. Pulmonary congestion is also supposed to be a manifestation of retrocedent gout in some cases ; and gouty pneumonia has been described. In connection with the *nervous system* gout may give rise to attacks of severe headache or vertigo ; delirium or even acute mania (*see* INSANITY IN SPECIAL DISEASES) ; epileptiform or convulsive fits ; cerebral or spinal meningitis ; acute neuralgia, either external or internal, and especially sciatica, probably due to neuritis ; or severe muscular cramps. Apoplexy from cerebral hæmorrhage has been attributed to suppressed or retrocedent gout, but this can only occur if the vessels of the brain are diseased. Cerebral congestion might give rise to a temporary apoplectic attack. Among the acute manifestations of irregular gout may be further mentioned certain skin-affections, as eczema, erythema, or urticaria ; affections of mucous membranes, such as the conjunctivæ and lachrymal passages ; functional renal disorder, with albuminuria, or irritability of the bladder ; and external local signs of inflammation, associated with uratic deposit.

Many of the more *chronic* symptoms associated with gout have already been pointed out, when speaking of its premonitory symptoms, and only certain special phenomena need be alluded to here. Chronic skin-diseases are of frequent occurrence, namely, psoriasis, chronic eczema, pruritus—

either local or general—and acne. These may alternate very distinctly with articular gout. The nails are sometimes peculiar, being coarse and fibrous, striated and fluted, or lined vertically. Their substance may grow thick and brittle. In some gouty subjects daily paroxysms of heat and redness of the nose, attended with severe itching and irritation, cause considerable annoyance or distress. Violent sneezing fits are common. Many of these individuals are also liable to chronic catarrh, affecting the throat and the air-passages; and special appearances of the throat, tongue, and teeth have been described. In course of time gouty patients often become permanently asthmatic, the lungs being emphysematous, and dry bronchial catarrh being established. Gravel or urinary calculus may give rise to symptoms; or those indicative of chronic urethritis or cystitis may be present; especially in persons advanced in years. Permanent disorders of sensation, or slight local paralysis, may result from chronic changes involving particular nerves. Gouty persons are usually very sensitive to pain. Certain affections of the eyes have been attributed to gout, and among them a form of gouty iritis, described by Hutchinson as coming on insidiously, and almost painlessly, and ending in destruction of the eye. Changes in the external auditory meatus may also be associated with this complaint.

With regard to *tophi*, these can be seen or felt, provided they are superficial. Those connected with the helix of the external ear are most common; but they may also be looked for in the sclerotic or eyelids, in the nose, and under the skin, in the region of tendinous aponeuroses, especially in the leg or thigh. Tophi are originally liquid, and if one is punctured at an early period, an opalescent or milky fluid escapes, which on microscopical examination is found to contain an abundance of delicate acicular crystals; subsequently they become more consistent, and ultimately quite solid and hard, being then made up entirely of these crystals, which are closely aggregated together and interlaced. Taking the ear as an illustration, at first a small elevation appears under the skin of the helix, like a vesicle, having a soft feel. This gradually hardens until finally a little bead-like or pearl-like body is formed, presenting a whitish colour as seen through the skin. In course of time the cutaneous covering may be destroyed, leaving the little concretion exposed; or this may even become detached and removed, so that only a small depression is left.

5. Symptoms due to Chronic Organic Diseases.—In addition to what has been stated under the preceding heading, it is only necessary to refer here to the renal and cardio-vascular changes which are associated with gout. Disease of the kidneys is indicated mainly by the changes in the urine, other symptoms of chronic Bright's disease being often very obscure. The cardiac lesions are revealed by their respective physical signs; and there may be symptoms, first of excessive cardiac action from hypertrophy, and subsequently of cardiac failure, as well as those of particular valvular lesions. The vascular changes are discovered on examination of the arteries; and by their effects upon the circulation. It is impossible to describe within the limits of this article the numerous symptoms resulting from the various chronic organic diseases which may develop during the progress of gout, and which in many cases ulti-

mately produce a very complicated clinical picture. See HEART; ARTERIES; and KIDNEYS.

DIAGNOSIS.—A distinct gouty diathesis or tendency may be present, which it is important to recognise, while the joints are quite free from any apparent mischief. In most cases, however, the diagnosis has to deal with the nature of an articular affection, and to determine whether this is gouty or not. The chief diseases from which gout has thus to be distinguished are acute or chronic rheumatism, rheumatoid arthritis, and possibly gonorrhoeal synovitis. The data upon which a conclusion has usually to be formed with regard to a first attack are the presence or absence of an hereditary tendency to gout, as well as its intensity; the age and sex of the patient; the social position, occupation, and previous habits; the presence or absence of any obvious cause for the attack, or of premonitory symptoms; the localisation and characters of the joint-affection; the general symptoms; the character of the urine; the duration of the illness; and the absence of any cardiac complication.

The diagnosis in subsequent attacks is generally easier. If the metatarso-phalangeal joint of the great toe is alone inflamed several times in succession, or even if only the smaller joints of the feet and hands are implicated, the diagnosis of gout is tolerably certain. Then the presence of the permanent articular changes induced by gout, and of tophi in other parts, is of material assistance. Moreover, the urine may give evidence of renal mischief. In very doubtful cases it might be desirable to raise a blister, or even to take a little blood from the patient, and endeavour to obtain crystals of uric acid from the serum. The Röntgen rays may afford decided help, tophi being more transparent than the bony outgrowths found in rheumatoid arthritis.

In distinguishing gout from acute rheumatism, the absence of any hereditary tendency to gout and the existence of a family predisposition to rheumatism are important facts. Moreover rheumatism occurs most frequently for the first time in early life, and is not uncommon even in young children. Though more common among males, it often attacks females. It is not favoured by the habits which generate or promote gout, and affects all classes of persons, but especially those who from their occupation are liable to be exposed to cold and wet. The joints involved are the middle-sized or the larger ones, several of which are generally implicated in succession during the illness, the rheumatic inflammation exhibiting an erratic character; the local symptoms tend to be less severe than in gout; there is less marked oedema about the joints, and no enlargement of the veins, or subsequent desquamation. It must not be overlooked, however, that gout may attack the middle-sized joints. Pyrexia is high as a rule in acute rheumatism, and is often quite out of proportion to the extent of the articular affection; while profuse acid perspiration is almost always a prominent phenomenon. In addition to other differences, chronic rheumatism is at once distinguished from gout by the entire absence of uratic deposits.

Rheumatoid arthritis is usually met with in females between twenty and forty years old. There is neither hereditary taint, nor a history of such habits as generate gout, but, on the contrary, the patients are generally poor, hard-worked, and badly fed; all joints seem to be equally liable to be affected, both large and small, and the local sym-

ptoms are not of a very acute character, though the pain may be very severe, but they tend to continue for a long period. The general symptoms are those of debility and anæmia; and Spender has drawn attention to certain early symptoms, especially cold hands and feet, constant dampness of the hands, pigmentation of the skin, and a rapid and compressible pulse. Rheumatoid arthritis is a disease which tends to progress, involving joint after joint, but it presents no periodicity in its attacks, and often advances without any intermission, as a subacute or chronic disease. Ultimately it often causes much deformity and crippling of the articulations, which creak and grate on movement, but this results from a very different pathological change from that which takes place in gout, for there is not the slightest deposit of urates, either in the joints or elsewhere; nor can any uric acid be obtained from the serum, even in the most extreme cases. The urine presents no special characters; and the kidneys are not diseased.

Gonorrhœal arthritis is distinguished from gout by the age of the patient; the distribution of the joint-affection; the absence of any tendency to recurrence, except in association with a fresh urethral discharge; and the different nature of the morbid changes, tophi never being formed.

As exceptional points bearing upon the diagnosis of articular gout, the following may be mentioned. It has happened that pyæmia beginning in the great toe has been mistaken for gout, but the progress of the case would soon clear up any doubt under such circumstances. Again, articular inflammation from injury might resemble gout; and, moreover, it must be borne in mind that such an injury may really set up gouty inflammation for the first time, so that the joint may not recover properly. In some individuals the ends of the phalanges of the fingers are enlarged, especially the terminal ones, and cause nodulations—*nodi digitorum*—which resemble those of gout, and are by some regarded as being of a gouty nature.

In any gouty case the detection of the organic diseases liable to be set up in its course is of great moment in diagnosis, especially renal and cardiovascular changes; and also the association with their proper cause of catarrhal affections, skin-diseases, and other complaints, when these are really of a gouty nature.

PROGNOSIS.—The first point relating to the prognosis of gout which calls for notice refers to the immediate dangers in any particular case. A simple acute attack of articular gout rarely, if ever, kills the patient. When, however, internal organs are implicated, the matter becomes much more serious, and a fatal result may occur, so that the prognosis must be a guarded one under such circumstances. The danger becomes much greater if the complaint has been long established, and if the kidneys or other important organs have become structurally diseased. Indeed, these diseases of organs are often themselves immediately dangerous. Again, any acute inflammation occurring in a confirmed gouty subject is the more serious on this account; and the same remark applies to injuries and shocks of all kinds.

In the next place, the future of a gouty patient has to be considered, as regards the prevention of subsequent attacks. It must always be recognised that gout is a recurrent affection, and complete immunity can never be guaranteed, when once the

complaint has declared itself. At the same time not a few cases have occurred in which there has been but one attack. In giving an opinion on this point, the prognosis in any individual case will depend upon:—1. The degree of hereditary tendency to gout. 2. The age of the patient; for the earlier the period at which the disease begins, the less hopeful is the prospect of a cure. 3. The time the complaint has lasted from its commencement, and the frequency and duration of the gouty fits. If gout has become established, and especially if distinct tophi have formed, it is quite impossible to eradicate it. 4. The habits, mode of living, and occupation of the patient. It is only when the patient is prepared to adhere strictly to proper rules of living that a cure can be hoped for. Those who in their occupation are tempted to drink much, or who are exposed to cold or wet, are much less likely to be cured. It may be remarked here that gouty subjects are less able than others to resist exposure.

Another point bearing upon prognosis refers to the duration of life in gouty persons. If the disease comes on late in life, and the paroxysms occur only at long intervals, while the organs are free from any organic mischief, gout may not appreciably shorten life, and the patients may even enjoy good health up to an extreme old age, provided they are sufficiently careful in their mode of living, and no accidental complications arise. Chronic gout does, however, unquestionably tend to shorten the duration of life, to a greater or less degree in proportion to its severity, and more especially to the indications present that the kidneys, heart, arteries, or other important structures are organically diseased. This tendency is important in relation to life-insurance.

It has been affirmed that gout is a protection against certain other diseases, such as phthisis and diabetes mellitus, but this statement does not rest on any scientific data.

TREATMENT.—Although there are certain well-defined principles applicable to the treatment of gout in its various phases, every case must be considered on its own merits. It will be convenient to discuss this part of the subject under certain general headings, premising that the administration of medicines is often the least important part of the treatment, and that the habits of life of the patient always need thorough supervision in all their details.

1. Preventive and Curative Treatment.

Individuals who have a marked hereditary predisposition to the complaint may, by careful attention to their mode of living, do much to diminish the severity of the disease in later life and to prevent even its appearance. In all cases the willing co-operation of the patient is essential to success.

(a) *Diet.*—Moderation in the quantity of food is the first point to be attended to in the treatment of the gouty diathesis. It is not necessary or desirable to restrict persons who are gouty to a very low diet, especially if they are in any way weak, but an amount sufficient for proper nourishment in each individual case may be allowed, and at no meal should the stomach be uncomfortably filled. The meals must be taken at regular times, and not hurriedly. Very late dinners, as well as suppers, should be prohibited, but it suits many persons better to dine at half-past six or seven o'clock than at midday. The nature of the food is highly

important. It is quite unnecessary, as some recommend, to restrict the patient absolutely to a vegetable diet, but a due proportion of animal and vegetable aliments should be allowed. At the same time, in persons who have any tendency to gout, an essential part of the treatment often consists in diminishing the amount of meat which they consume, and they should not take it more than once a day. Indeed, the aim must be to reduce all kinds of proteid food, whether animal or vegetable, to such an amount as the system can satisfactorily dispose of, with due regard to the proper nutrition and strength of the body. As regards the kinds of animal food which are suitable for gouty subjects, white fish, chicken or fowl, game, tripe, and mutton are the best forms. Sweetbread is generally recommended, but it has been recently laid down that sweetbread and similar tissues rich in nuclein should be rigorously excluded. Soups had better be avoided, or should only be taken in very small quantity. Tender and underdone beef may be taken in moderation from time to time, if it is readily digested. Pork or veal, dried and salted meats, and rich dishes of all kinds, should be avoided. Lightly boiled or poached eggs may be permitted. Some authorities regard fats and milk as important elements in the diet of gouty patients, but this is a matter of personal experience. Vegetables which contain much woody fibre, or which create flatulence, must be eschewed; and certain articles such as rhubarb, tomatoes, especially when cooked, asparagus, and sorrel, are often injurious to the gouty. Those who are subject to gout should either abstain altogether from, or only take a very limited quantity of, sugar and saccharine articles of diet. Hence, although digestible fruits may often be taken with advantage in moderation, those which are very sweet must be used with particular caution. Stewed and baked fruits often agree well, but fruit-tarts, and, indeed, pastry of all kinds, should be interdicted. The juice of oranges or lemons is considered beneficial for gouty persons. Starchy foods are permissible in moderation. It may be laid down as a rule to be invariably followed, that gouty patients should limit themselves to simple meals, and not indulge in a number of 'courses;' and that they should avoid condiments and salt, as well as everything which is in their case indigestible.

(b) *Drink*.—No rules can be laid down applicable to all cases, but there are certain broad principles which have to be borne in mind. An abundance of good and pure drinking-water is to be commended, but it should be taken mainly apart from meals. It is a good plan for the subjects of gout to take a tumblerful of either cold or hot water before retiring to rest at night. Effervescent potass- or lithia-water may be substituted for ordinary water with advantage, but not soda-water. One or other of the natural 'table-waters' may also be allowed if desired. Tea and coffee may be taken in moderation, provided they do not disagree. With reference to alcoholic drinks, in a considerable number of instances one of the first objects in the treatment of the gouty diathesis should be the regulation of the use of this class of beverages. This indication is obvious enough when the condition is evidently due mainly to intemperance; but even when the patient is temperate, it may be that in his case the amount consumed needs to be reduced, or total abstinence

enforced, especially if there should be a strong hereditary predisposition to gout, or if the complaint appears in early life. Some patients are undoubtedly better if they abstain entirely from stimulants; others, however, can take those of a proper kind, and of good quality, in strict moderation, with advantage. It may be laid down as a general rule that malt-liquors and all stronger wines are injurious, and should be interdicted. Those which are most suitable are sound light claret, hock, moselle, chablis, or sauterne. A small quantity of good dry sherry suits some gouty patients very well. A little brandy, well diluted, often agrees better than any other kind of alcoholic liquor; in other cases whisky or gin answers best. Whatever stimulant is selected, it should only be taken at meal-times. Persons who are distinctly gouty should avoid excess on every occasion; and even if they do not invariably abstain from alcohol, they may find it beneficial to do so for limited periods, especially if there is a tendency to the development of gouty symptoms. It may be mentioned here that the treatment of selected cases of gout by an exclusive meat-diet, with an abundance of hot water, has been advocated.

(c) *General hygiene*.—Sedentary habits must be combated, whether due to occupation or indolence; and it must be insisted upon that a due amount of outdoor exercise is taken daily, although prolonged exertion, tending to cause fatigue and exhaustion, must be avoided. Walking and horse-exercise are highly beneficial, especially in the case of those who live rather too freely. Even carriage exercise is useful, so that the patient may have the benefit of the fresh air. For those who cannot have much regular exercise, cycling, lawn-tennis, fencing or single-stick, golf, and the like may be serviceable. As bearing upon the prevention of an acute fit of gout, it is an undoubted fact that some individuals who are subject to the disease seem to be able to ward it off by walking, riding, or adopting some other form of prolonged and violent exercise on the first intimation of a threatened attack. Gouty persons should rise early in the morning and avoid late hours. They should be relieved from excessive mental labour, or any great strain upon the mental faculties, but especially from worry and anxiety of all kinds. Attention must be paid to the cutaneous functions, the surface of the body being also protected from the injurious effects of cold. Warm clothing should be worn, in keeping with the weather, and those who can bear it should wear flannel next the skin. With regard to baths, many gouty persons are decidedly the better for using a cold or tepid bath every morning, followed by energetic friction; in other cases the employment of the warm bath at intervals, or of the Turkish bath, answers best. A course of treatment in a hydropathic establishment from time to time, under due medical supervision, is sometimes decidedly beneficial. Climate demands attention, whenever the circumstances of the patient allow a choice to be made. It may be advisable for gouty subjects to reside permanently in some warm and equable climate, or at any rate during the winter and early spring. In this way attacks may often be warded off, and the disease thus prevented from making progress. Those who are obliged to remain in England during the inclement seasons should avoid exposure to wet and cold, as well as sudden changes of temperature, and night-air. The bedroom should

be warm and well ventilated ; and in cold weather it is desirable to keep a fire burning during the night. Unduly heated and badly ventilated rooms, as well as crowded places of public resort, must be avoided.

(d) *Medicinal treatment.*—There can be no doubt but that the judicious use of certain medicines may assist materially in warding off or mitigating the gouty condition, and in preventing the occurrence of acute paroxysms. The digestive functions demand particular attention, and medicines which help these functions are often of the greatest service, if required. A course of alkalis or acids, according to the indications in each case, may prove most serviceable, combined with some simple bitter infusion or tincture, but acids must be employed with caution. Salts of potassium and lithium are used for special purposes in gout, but how they act is a matter of controversy, and cannot be discussed here. The bicarbonate of potassium, carbonate of lithium, or the citrates are the best salts to administer. They should be taken well diluted, and on an empty stomach. Magnesia or its carbonate may be given with advantage if there is much acidity, and if the bowels are habitually constipated. Saline aperients are often of great service, and they may be usefully administered in small doses, freely diluted, and regularly repeated, in order that they may act on the kidneys. In many cases other aperients may be employed at intervals with advantage, but strong purgatives must be used with particular caution. An occasional dose of blue-pill, calomel, or other cholagogues may be decidedly beneficial.

(e) *Mineral waters and baths.*—Certain mineral waters are of great value in the treatment of the gouty diathesis, when employed under proper medical supervision, and patients will often use them when they will not undergo a course of regular medicinal treatment ; while the water thus taken internally is itself of service. Space will not permit any lengthy discussion of this subject here, and it must suffice to mention that the kind of mineral water that suits one patient may be highly injurious to another. These waters are employed both internally and in the form of baths. Those chiefly used in gouty conditions are the waters of Bath, Buxton, Cheltenham, Clifton, Harrogate, Leamington, Malvern, Woodhall Spa, and Droitwich, in England ; Strathpeffer and Moffat in Scotland ; Llandrindod, Llangamarch, and Llanwrtyd in Wales ; Lisdoonvarna and Lucan in Ireland ; and Carlsbad, Marienbad, Vichy, Wiesbaden, Baden-Baden, Ems, Royat, Aix-la-Chapelle, Aix-les-Bains, Evian-les-Bains, Contrexéville, Dax, La Bourboule, Luchon, Kreuznach, Naheim, Ischl, Friedrichshall, Hunyadi János, Pullna, Schlangenbad, Teplitz, Seidlitz, Homburg, Kissingen, Rubinat, Wildbad, Ragatz, Gastein, Elster, Tarasp, Apollinaris, and other continental waters. Some of these may be taken regularly or at intervals, for the purposes which they respectively fulfil ; or, if circumstances permit, a systematic course of treatment from time to time, at certain of the places mentioned, may be recommended. See MINERAL WATERS.

2. *Treatment of Acute Gout.*—When a fit of acute articular gout sets in, our objects should be to shorten the attack ; to restore the affected parts as nearly as possible to their normal condition ; and to relieve symptoms. In the first place, particular attention must be paid to the *diet*. The aim should be to make this as low as is compatible with the

condition of the patient, especially if the fit is of a very acute type. In young and strong patients the diet should at first consist of milk, farinaceous articles, and abundance of water, barley-water, or toast-and-water. Those who are advanced in years, weak, or broken-down in health, or who have long suffered from gout, require a more nutritious diet, but it should be easily digestible, consisting of beef-tea and good soups, milk, and eggs beaten up, the quantities being regulated by the requirements of each case. As the symptoms subside, the food should be gradually improved, white fish, fowl, and meat being allowed in succession, but in strict moderation. If possible all kinds of alcoholic stimulants should be interdicted, but it may not be judicious to cut them off entirely in some cases, either on account of the previous habits or present condition of the patient, and then it is best to give a definite quantity of brandy or whisky, well diluted, with the food. For those who cannot take spirits, a little good hock or sauterne answers well. Under exceptional circumstances the writer has given a moderate quantity of good champagne even in acute gout with decided advantage.

As regards *medicinal* agents, colchicum has long held a most prominent place in the treatment of acute gout, and is commonly regarded as a specific. There can be no doubt as to the influence of this drug in relieving the symptoms and shortening the paroxysm of gout. Its effects must be watched, however, for it does not agree in every case. It has been alleged that colchicum renders the patient more liable to subsequent attacks of gout, but for this notion there does not seem to be any real foundation. The tincture or wine of colchicum may be given in doses of ten to twenty or even twenty-five minims every four or six hours, and either of these preparations may be combined with the citrate or bicarbonate of potassium or with a salt of lithium. Garrod considers that guaiaicum, though less potent than colchicum, has considerable power in relieving gouty inflammation and may be given when fever is absent.

Salicylates, especially salicylate of sodium, have been much recommended in the treatment of acute gout, and may sometimes be advantageously combined with the agents just mentioned. They certainly have proved useful in the writer's experience. Another class of drugs employed are phenazone, acetanilide, and allied agents, but they are not to be recommended. A group of remedies, much advocated of recent years on account of their remarkable solvent powers over uric acid outside the body, consists of piperazine, lysidine, lycetol, and allied agents. They have, however, by no means fulfilled the expectations formed with regard to them in the treatment of gout, and in the writer's experience, as well as in that of many other observers, have signally failed. Among special treatments inhalation of oxygen has been advocated in the treatment of acute gout.

It is necessary to keep the bowels acting freely by means of suitable aperients, and saline purgatives are of considerable value for this purpose. Other aperients, such as compound rhubarb pill, colocynth, resin or tincture of podophyllum, calomel or blue-pill, may be employed in appropriate cases. Diluents may be given freely, in order to promote the action of the kidneys ; and if the cutaneous functions appear to be defective, some mild diaphoretic may be administered, or it may even be desirable to employ the hot-air or vapour-bath.

Medicines may be needed for the relief of symptoms, especially pain and sleeplessness, for which Dover's powder or other preparations of opium, belladonna, chloral hydrate, sulphonal, or bromides may be indicated, but they must be used with discretion. In very severe cases the hypodermic injection of morphine is of much service.

Local treatment.—The affected parts in acute gout should be kept entirely at rest, and placed in a comfortable position, supported by pillows, and either horizontal or elevated, according to the feelings of the patient. In ordinary cases it is sufficient to wrap up the joints in flannel, or to surround them with cotton-wool completely covered with oil-silk or gutta-percha sheeting, according to Garrod's method. If the pain is considerable, other local applications might be used, of which most efficient are warm fomentations, to which tincture of opium or belladonna may be added, poppy-fomentations, lead-and-opium lotion, localised steaming, belladonna liniment, tincture of aconite, or a solution containing morphine and atropine. Some practitioners prefer evaporating lotions containing alcohol, ether, or chloroform; others warm-water compresses. A blister in the neighbourhood of a gouty joint may be of service, if the attack be asthenic, and also should effusion or much stiffness persist. During recovery, benefit may be derived from careful friction with some stimulating liniment, application of iodine, shampooing, gentle passive movements, douching with salt and water, or the application of a light bandage or elastic support, should there be a tendency to permanent thickening and stiffness, or to œdema and enlargement of the veins.

Cases of acute articular gout have been successfully treated by the Tallerman hot-air baths, and these are certainly worthy of more extensive trial. It is affirmed that subacute gout has been treated successfully by massage and galvanism combined.

The acute forms of *irregular gout* must be treated according to their nature, and here it must suffice to offer a few general remarks on the subject. If serious internal symptoms arise, which are distinctly of a gouty nature, and especially if they occur as retrocedent phenomena, it is important to try to excite inflammation in the joints, by means of local heat, friction, and sinapisms. Colchicum may be of service in the non-articular, as well as in the articular form of gout. In painful affections opium or other anodynes are called for; and frequently the administration of alcohol and other stimulants is indicated, with antispasmodics, such as ammonia, ethers, camphor, musk, or belladonna, especially when the stomach or heart is affected. In conditions attended with signs of much depression or collapse, external heat may be applied over the body, or sinapisms to the limbs and over the cardiac region. In the treatment of inflammatory diseases associated with gout much care is required, especially in resorting to depletory measures.

3. Treatment of Chronic Gout.—When gout becomes an established chronic disease, the same general rules of treatment are to be observed as in the prevention or attempted cure of the complaint. Similar medicinal remedies are also indicated, lithium-salts being particularly valuable, and they may even aid in removing gouty deposits; but others may be added to the list, which are suitable in different cases. Colchicum is often of much service, taken habitually or from time to

time, in the form of the extract at night, or a few minims of the tincture or wine two or three times a day, combined with other medicines. Among the many therapeutic agents recommended in the treatment of chronic gout under different circumstances may be mentioned benzoic acid or benzoate of ammonium, phosphate of ammonium or of sodium, iodide of potassium, bromide of potassium, carbonate of aluminium, lime-juice, guaiacum, ammoniacum, and tonics, especially quinine, tincture or infusion of cinchona, ferruginous preparations, and arsenic. Undoubtedly most of these are of use in appropriate cases of chronic gout, to serve their special purposes, but they must be used judiciously, especially iron. Garrod strongly advocates the administration of guaiacum in chronic gout, and for the purpose of averting acute attacks. If it causes intestinal irritation, he gives serpentary as a substitute. Symptoms connected with various organs frequently call for attention, and must be treated by appropriate remedies. Should diarrhoea set in, it must not be hastily arrested, as this may be a mode of relief to the system. With regard to the local conditions in chronic gout, the prolonged use of some of the mineral waters previously mentioned, both internally and in the form of baths, such as those of Aix-la-Chapelle, Aix-les-Bains, Homburg, and Baden-Baden, or definite treatment in various spas, not forgetting Droitwich in this country, may succeed in removing to some extent deposits of urates, and in diminishing stiffness and thickening of joints. For these purposes local measures may also be of service provided the morbid changes are not too far advanced, namely, occasional blistering or application of iodine; the prolonged use of wet bandages; friction with liniments; shampooing and passive movements; or systematic compression by means of some non-irritating plaster. Solutions of alkalis or alkaline carbonates, and especially of carbonate of lithium, have been kept applied to gouty joints and other parts for a long time, under the belief that deposits of urates may be thus dissolved. Massage, electricity, and the modern hot-air treatment have their advocates. Superficial uratic deposits should not be interfered with unless they become troublesome, when it may be desirable to puncture the skin and let the contents out. The propriety of removing large masses by operation may come up for consideration, but this should only be attempted if there is every probability that they can be entirely removed without any serious difficulty, and if the patient is in a fit state for the operation. When abscesses or ulcers form, they come under the treatment of the surgeon; but it may be observed that simple aseptic dressings usually answer best in these cases, and they may sometimes be advantageously dressed with a solution of carbonate of potassium or lithium. Under any treatment it is by no means an easy matter to induce lesions of this kind to heal in cases of chronic gout.

The treatment of the various chronic organic diseases which are liable to arise in the course of gout must always be kept in mind, but the reader is referred to other appropriate articles for a consideration of this part of the subject.

FREDERICK T. ROBERTS.

GRAIN-POISONING.—See ACTINOMYCOSIS; ERGOTISM; and PELLAGRA.

GRAM'S STAIN for BACTERIA.—*See* BACTERIA, p. 132.

GRAND MAL (Fr.).—A term applied to epilepsy when it assumes the form of a severe convulsive attack. *See* EPILEPSY.

GRANULAR DEGENERATION.—*See* DEGENERATION.

GRANULAR KIDNEY.—A morbid condition of the kidney, in which this organ is the seat of fibroid change, and as a result becomes contracted, hard, and granular. *See* KIDNEYS.

GRANULATION (*granulum*, a little grain).—The term 'granulations' is applied to small vascular prominences, consisting of embryonic tissue, growing on the surface of wounds or healing ulcers, by which the reparative process is carried on—whence the expression 'healing by granulation.' *See* WOUNDS, Healing of.

GRAVEL.—**DEFINITION.**—The deposit in and escape from the urinary passages of gritty particles.

VARIETIES.—Gravel may be composed of (1) uric acid and its compounds; (2) oxalate of lime; (3) phosphate of lime; or (4) the triple phosphate of ammonium and magnesium. By far the most common form of gravel is uric acid. This, owing chiefly to its great insolubility, is frequently deposited in the kidney and bladder, and is seen in the newly passed urine in the form of the well-known reddish-brown crystals, often described as resembling grains of cayenne-pepper. The supernatant urine is generally clear, rather dark in colour, and of a distinctly acid reaction. *See* OXALIC-ACID DIATHESIS; PHOSPHATIC DIATHESIS; and URIC-ACID DIATHESIS.

SYMPTOMS.—The passage of *uric-acid* crystals or gravel frequently causes no subjective symptoms, and is consistent with perfect health. Sometimes, however, it gives rise to, or is accompanied by, both general and local disturbance of function. The general symptoms are those of dyspepsia. Locally, there is dull aching in the lumbar region, not increased by movement; frequent micturition; a sense of heat and irritation at the neck of the bladder and along the urethra, especially during and after voiding water; and sometimes the appearance of a faint cloud of mucus or a slight tinge of blood in the urine.

TREATMENT.—From what has been said, it follows that the most important points in the treatment of gravel are strict limitation as to the *quantity*

of food; the avoidance of highly seasoned, very rich, or sweet dishes; the preference for vegetable rather than for animal food; abundant exercise in country air; and abstention from or the very sparing use of alcoholic liquors. Medicinally there may be given diuretics to increase the quantity of the urine, and facilitate the escape of gravel; pure water, alkalis, and alkaline waters freely diluted, to prevent the precipitation of uric acid; and saline aperients and saline waters, to promote digestion, and assist in ensuring the free action of the liver and alimentary canal. *See* CONCRETIONS. W. CADGE.

GRAVES'S DISEASE.—*See* EXOPHTHALMIC GOITRE.

GREEN SICKNESS.—A popular synonym for chlorosis, applied on account of the greenish colour of the skin sometimes present in that disease. *See* CHLOROSIS.

GRINDERS' ROT.—*See* PNEUMOCONIOSIS.

GRIPPE (Fr.).—A French synonym for influenza. *See* INFLUENZA.

GRUTUM.—*See* MILIUM.

GUINEA-WORM.—*See* ENTOZOA.

GUMBOIL.—*See* MOUTH, Diseases of.

GUMMA (Lat., gum).—A growth occurring in syphilis, so named on account of its supposed resemblance to gum. *See* SYPHILIS.

GUMS, Diseases of.—*See* MOUTH, Diseases of.

GURGLING.—A physical sign heard on auscultation of the chest or abdomen in certain conditions, due to the movement of gas and fluid within a cavity, whether normal or abnormal. A gurgling sensation may also be felt at times in the intestines, as over the cæcum in typhoid fever. *See* PHYSICAL EXAMINATION.

GUTTA ROSEA (*gutta*, a drop; *rosea*, rosy).—A synonym for acne rosacea. *See* ACNE ROSACEA.

GYMNASTICS (*γυμνός*, naked).—*See* EXERCISE.

GYNÆCOLOGY (*γυνή*, a woman; and *λόγος*, a word).—This term signifies the study of the diseases peculiar to women. *See* UTERUS; OVARIES; FALLOPIAN TUBES; MENSES; &c.

H

HABITS.—**SYNON.**: Drug-habits. — **DEFINITION.**—The conditions produced by the continuous self-administration of certain drugs on account of the pleasurable sensations at first produced by them. After a time the drug is continued not so much in order to obtain its pleasurable effects, which become less and less marked, as to avoid the depression and unpleasant sense of want which follow its discontinuance.

The following 'habits' will be considered: Arsenic; Cannabis Indica; Chloral Hydrate; Chloroform; Cocaine; Ether; Morphine; and Paraldehyde. For Sulphonal, Trional, and Antipyrine *see* SULPHONALISM.

Arsenic-habit.—Excepting in the arsenic mines of Cornwall the drug is not often taken in this country as a habit. In other cases the habit generally originates during the treatment of some skin-

affection or other chronic disorder. In Styria whole families take arsenic to counteract the fatigue of mountain-climbing.

Habitués will take four to eight grains or more for a dose without ill-effects, while these are brought on by minute doses in other persons. Among those who can take the drug with impunity the effects produced are exhilaration without intoxication, a sallow, waxlike complexion, and some depression in the interval between the doses. For the symptoms of chronic arsenical poisoning see p. 99.

TREATMENT.—In mild cases, and when the drug has not been taken for any length of time, it should be at once withdrawn; but in old-standing cases the dose should be gradually reduced; for a fatal issue has followed the sudden discontinuance of the drug.

Cannabis Indica-habit.—This drug is largely used in India, Egypt, and other Eastern countries. It is chewed, smoked, and taken with alcoholic liquors. The preparations of the drug used are Bhang, Haschisch, and Ganji.

When symptoms arise they take the form of dyspeptic troubles, anæmia, wasting, and mental enfeeblement, and may terminate in chronic insanity and death.

The *treatment* is conducted on the same principles as in the case of the Morphine-habit (p. 611).

Chloral-Hydrate habit.—This is commenced almost invariably on account of insomnia, and continued in order that sleep may be obtained and the physical distress caused by the discontinuance of the drug avoided. The *dose* is a matter of idiosyncrasy. Some can take forty grains or more nightly without ill-effect; others are highly susceptible to the action of the drug. The amount taken is not as a rule continually progressive. The largest recorded daily dose was 300 grains.

SYMPTOMS.—There is produced a dull, apathetic, listless condition, with intellectual foginess, feeble will-power, and a muddled mental state, sometimes with hallucinations. The heart's action becomes feeble; the pulse rapid, weak, and soft; and the extremities cold. Digestive troubles and dyspnoea are complained of. There is muscular weakness, chiefly affecting the lower extremities, which may proceed to such an extreme degree that a condition resembling paraplegia may be produced. As a result of the vasomotor disturbance the skin is liable to urticaria, diffuse inflammatory erythema, and bullous eruptions; ulceration of the nails may occur. Albuminuria and a spurious glycosuria may be found (see GLYCURONIC ACID). If the drug be suddenly discontinued there is not the same amount of depression as is produced by a sudden cessation of the Cocaine- or the Morphine-habit; but in a case with well-marked symptoms the sufferings endured from sudden inhibition of the drug are severe.

The *Prognosis* is more favourable than in the Cocaine- or the Morphine-habit.

TREATMENT.—The patient should be placed in bed in a warm room. The drug should be reduced rapidly, and altogether abandoned in less than a week. In a mild case immediate withdrawal can be practised. If cardiac tonics are needed, strychnine, digitalis, or sparteine may be given in ordinary doses. Alcohol should not be employed; for, although it is usually taken by those who have the chloral-hydrate habit, it is not well borne, and may produce dangerous depression. Hot coffee should

be given freely; and caffeine, with or without phenacetin or antipyrine, will be found of service for the headaches, neuralgias, and flushes that may distress the patient. Massage and the hot pack will assist in combating insomnia, and a change of scene and air will be beneficial.

Chloroform-habit.—Chloroform may be inhaled for pain or out of curiosity. The *dose* is generally unknown, the amount being rarely measured. A pint a day has been used. Fatal termination from an overdose is not uncommon.

SYMPTOMS.—The effects produced by the drug are at first everything that is delightful. A series of brilliant images and gorgeous pictures fill the imagination, each vision more beautiful than the last. After a time the pleasurable sensations fail to appear, and the victim experiences nothing but terrible nightmares. The general symptoms are nausea, flatulence, diarrhoea, enfeeblement of the heart, coldness of the extremities, and other conditions due to sluggish circulation and lowered vitality, together with mental anxiety and nervous depression.

TREATMENT.—This should be similar to that adopted for the chloral-hydrate habit; but the chloroform should be stopped at once.

Cocaine-habit.—Cocaine is taken as snuff, in wine, hypodermically, or by mouth to ease pain and distress, and to allay hunger and fatigue; the drug is continued at first for pleasure, and later because the unappeased desire causes suffering. Among the cases which have come under the notice of the writer the daily *dose* ranged from 5 to 50 grains. A daily dose of 90 gr. has been recorded.

SYMPTOMS.—At first the effects are wholly agreeable. They consist of a rapid relief from pain and worries, a sense of elation, new life, vigour, and increased mental power; but the mental and bodily collapse supervenes far more speedily than in addition to morphine.

A little later, the main symptoms are loss of weight, dyspepsia, anorexia—though occasionally the appetite is ravenous—constipation, restlessness, a peculiar inability to attend for more than a few minutes at a time to any one occupation, and talkativeness, which, together with dilatation, and insensitiveness of the pupils, follows on a full dose. Sleeplessness and intense depression occur if the accustomed dose is not obtainable.

Later on, after a full dose, there will still be intellectual exaltation, brilliancy of discourse, and a loss of the sense of time, followed shortly by a dull, moody, dissatisfied, and limp mental condition—symptoms indicating the evanescent character of the intoxication. To escape the recurrence of the depression the drug is taken more frequently; and in a few months symptoms of profound degeneration and debility will appear. The face becomes cadaveric, the eyes sunken, the body wasted; there is trembling, nervousness, and insomnia; the memory is deficient, and there may be distressing attacks of dyspnoea and palpitation, noises in the ears, hallucinations, muscular twitchings, tonic or clonic spasms, or even epileptiform convulsions which may prove fatal. Impotence is the rule, but it may be accompanied by easily roused sexual excitement. Albuminuria may be present. There is itching of the skin, and the sufferer may lacerate his skin not only on account of the irritation, but to try to rid himself of insects (the 'Cocaine bug,' as it is termed in America) which he fancies are crawling about his skin. A stage is sometimes reached when

there is a fear of being alone, yet a distrust of all companions; and a melancholic or maniacal condition may arise, which may continue for some time after the drug has been abandoned.

When the cocaine-habit is suspected, the body should be examined for needle-marks and abscess-scars, which are similar to those found in morphine-habitués. A stage of want can be produced in a few hours, as advised under the morphine-habit, and the urine can be analysed for cocaine.

PROGNOSIS.—Cocaine, being the more attractive drug, is not so readily given up as morphine, but the conditions affecting the prognosis are identical.

TREATMENT.—The reduction of the daily dose should be spread over 2 to 20 days, according to the symptoms and the severity of the case. Bromides may be given on lines laid down under 'Morphine-habit.' Strychnine should be given: as hypnotics, morphine and paraldehyde are useful. For detailed treatment, the restlessness, neuralgias, and other symptoms, see 'Morphine-habit.'

Ether-habit.—Ether prepared from methylated spirit is generally used. The habit is met with in the north of Ireland. A dose 1 to 4 drachms or more is taken neat, preceded and followed by a draught of water.

SYMPTOMS.—Intoxication of a quarrelsome type rapidly appears; coma and subsequent sobriety follow, all in a period of about 2 hours. The process can be, and often is, repeated several times during one day. As a rule there are no ill-effects. In chronic cases the symptoms are similar to those produced by chronic alcoholism.

The treatment is the same as that for Alcoholism (see p. 42).

Morphine-habit.—**SYNON.**: Morphinomania; Opium-habit; Fr. *Morphinomanie*; Ger. *Morphiumsucht*.

The habit of taking morphine or opium is usually commenced for the relief of pain or insomnia. Opium-smoking is due to curiosity or the example of others. Laudanum-drinking is sometimes resorted to as an antidote to ague or rheumatism. The dose of morphine partaken of varies from 1 to 100 grains daily; of solid opium to over 100 grains daily. One pint of laudanum has been known to be taken daily.

SYMPTOMS.—The symptoms vary according to idiosyncrasy: no apparent ill-effects occur in some persons who take large doses for a length of time; in others, pronounced effects arise in a few weeks or months.

The face becomes pale or sallow; there is a peculiar aged appearance and greyness; the features are pinched and the figure bent; while emaciation and general aspect suggest malignant cachexia. The pupils are contracted after a dose: in the stage of want they may appear normal, dilated, or unequal, with defective accommodation. The conjunctivæ are at times congested, and the eyes sunken and glassy, with a dreamy, 'far-away' expression. After a large dose there may be huskiness of voice. The teeth become loose and decayed. The hair becomes grey and falls off. Although at first, and especially after a dose, there is increased mental activity and intellectual brilliancy, the memory becomes impaired, particularly for recent events. The appetite is at one time insatiable, at another absent. Constipation is the rule, but diarrhœa and a chronic dysenteric condition may arise, especially in the stage of want. Sexual desire is at first in-

creased, later absent. In females there is amenorrhœa: the pregnant woman is liable to abort. The virile power and the menstrual flow usually reappear shortly after the drug has been discontinued. Albuminuria may be present and may continue many weeks after the drug has been discontinued.

Sleep is fitful and uncertain. Lassitude and restlessness alternate with wakefulness and activity. Neuralgias occur, and a condition resembling ague may be experienced. Moral as well as physical degeneration ensues. The truthful, upright man may become unreliable and utterly untruthful. Indeed, the untruthfulness of drug-inebriates generally is proverbial. There may be hallucinations and delusions, and a state resembling *petit mal* may arise, during which criminal acts may be performed. Apart from this condition, it is not unusual for resort to be had to lying, cheating, and stealing, if the drug be otherwise unobtainable. As an aid to diagnosis the body should be examined for needle-marks (indurated and often discoloured patches, mostly circular), which, in old-standing cases of hypodermic injection, will cover the body. Scars of abscesses of various shapes will probably be found in chronic cases. These latter are not nearly so frequently found among patients who employ morphine in some form which requires warming before use. If this examination be not permitted, a stage of want may perhaps be brought about by keeping watch on the patient's movements for a few hours, and by stopping all possible channels of supply; but the watcher must be acutely observant, as the majority of drug-takers resort to innumerable devices to keep their habit secret and to guard against deprivation. The urine may be examined by the iodic-acid test. Morphine may be found in the urine 5 to 8 days after the drug has been discontinued; if found after this time it is certain that the patient is still taking the drug. Morphine may also be found in the feces. In cases where the drug is not being taken by the mouth or hypodermically it may be smoked in an ordinary tobacco-pipe or mixed up with tobacco in a cigarette, or introduced *per rectum*. See URINE, morbid conditions of.

The symptoms of sudden withdrawal indicate the intensity of the suffering. A stage of want is evinced by extreme restlessness, neuralgia and insomnia. If the withdrawal be continued, the secreting glands become abnormally active as shown by running at the eyes and nose, gastritis, diarrhœa, vomiting, cramps, and excruciating pains.

In 6 to 12 hours a condition resembling delirium tremens with hallucinations may arise, or even an acutely maniacal state which may persist for 48 hours. Sudden collapse and death have been known to occur.

PROGNOSIS.—The longer the drug-habit has lasted the more likelihood is there of a relapse. The daily amount of drug taken does not affect the ultimate result; the habit of short duration and large dose is more curable than that of long duration and small dose.

If the cause of the original habit be not removed, or if it subsequently return, it is probable that the habit will also be resumed.

TREATMENT.—The aim of treatment should be to reduce the drug rapidly and with as little suffering to the patient as possible. As immediate withdrawal entails violent suffering, some danger, a tedious convalescence, and results no more satis-

factory than those obtained by less heroic methods, this plan should only be employed for mild cases, in the young and strong, where the daily amount (if injected) is less than 5 grains.

Rapid withdrawal is advocated by Mattison of New York, and is an excellent procedure. Briefly, it is carried out as follows: with or without previous administration of bromides, reduce the morphine at once to $\frac{1}{4}$ or $\frac{1}{5}$ of the usual daily allowance, and in every case administer the drug by the mouth. Give bromide of sodium (30 grains) twice daily. Each day increase the daily doses of bromide by 20 grains, until on the ninth day two doses of 100 grains each are given. Gradually lessen the opiate till on the eighth to the tenth day it is entirely abandoned. On the day its regular use is discontinued, give at night $\frac{1}{4}$ of former (i.e. before treatment commenced) entire daily amount of morphine, on the next night $\frac{2}{5}$ of this dose, and on the following night $\frac{1}{3}$ of the first night's dose. With each of these doses give a maximum dose of bromide. Twenty-four hours after the last dose of opiate, put patient in bed and keep him there two to four days. Any other symptoms must be treated as they arise. A subsequent dose or two of morphine (by the mouth) may be required for insomnia if other remedies fail. The treatment must to some extent vary with each case. The writer has sometimes employed far larger doses of bromide with advantage.

The *slow method*, extending over weeks or months, may be employed if, owing to organic disease, rapid reduction of the opiate is considered unsuitable. Oscar Jennings of Paris has demonstrated with the aid of sphygmographic pulse-tracings that digitalis, sparteine, and trinitrin have a very similar effect on the pulse of a morphine-habitué to that brought about by a dose of morphine. At the commencement of the treatment he reduces morphine by about $\frac{1}{4}$ of the customary daily quantity, and then by 1 grain or less each day. He gives digitalis as soon as the heart becomes sluggish. When a daily dose of about 2 grains of morphine is reached, for every sixth of a grain reduced (in the case of syringe-users), double that quantity is given by the mouth or rectum. By this means the syringe is shortly abandoned. The internal doses are then gradually reduced to zero.

Whatever method is adopted, it will be found almost impossible to keep satisfactory control over a patient in his own house, and if this be attempted, the result is generally discouraging to the medical attendant, the patient, and the friends. Wherever the treatment be carried out, the attendants must be ever on the alert against deception.

Every patient who wishes to be cured of his habit must be prepared to endure some suffering. Hare truly says, 'When a patient goes through the withdrawal without suffering, you need not flatter yourself that it is on account of your treatment; it is because he has a secret supply of his drug.' We must therefore expect to be called on to minister to a variety of ailments, the chief among which will be restlessness, insomnia, neuralgias, and digestive troubles. For restlessness the hammock, as first recommended by Jennings, is useful; for the insomnia and neuralgias various remedies are required. Both in the morphine- and the cocaine-habit, in the early stages of treatment, chloral-hydrate is apt to produce excitement instead of repose. It can be used in the later stages. Hot-air baths, massage,

and electricity will be at times beneficial for all the above symptoms. For digestive troubles soda and bismuth, rhubarb and soda, capsicum, hot-water enemata, hot fomentations, and especially milk-diet will be found of service. If stimulants are required, caffeine, kola, and ammonia should be employed—not alcohol. The writer has never found it necessary to administer alcohol to any case of drug-habit. Too often the drug-inebriate has been an alcohol-inebriate, and in any case he is readily converted into one. Every drug-patient should be warned against the use of alcohol. Tonics, especially strychnine, quinine, and iron, will be required. A sea-voyage under supervision, and perhaps a prolonged rest from all work, may be indicated when active treatment is suspended.

Paraldehyde-habit.—Employed for insomnia and continued on account of the sleeplessness and depression which may follow the disuse of the drug. The dose taken after several months' habit varies from one to six ounces daily.

SYMPTOMS.—The principal symptoms are loss of flesh, digestive troubles, the odour of the drug in the breath, palpitation and irregularity of heart, muscular tremors and inco-ordination, and insomnia. A condition resembling delirium tremens may be present.

TREATMENT.—This consists in the immediate withdrawal of the drug. Sleep must, however, be secured. For this purpose, bromide of potassium should be given freely. Five drachms or more may be required before bed-time. At bed-time chloral hydrate should be given in a 20- to 25-grain dose, followed, if required, by a smaller dose three hours later with a drachm of bromide of potassium. Sp. Ammon. Aromat. in 2-drachm doses should be given with each large dose of bromide, and two or three times during the night if the patient wakes and requires a stimulant. On the following day bromide of potassium may be required in 10- to 20-grain doses with Sp. Ammon. Aromat. \mathfrak{zss} . every two hours; and perhaps Pot. Brom. \mathfrak{zj} – \mathfrak{zj} . with chloral hydrate at night. Later a tonic treatment of strychnine and quinine will be required. Alcohol should not be given.

Sulphonal, Trional, Antipyrine.—With any of these drugs, 'habit' may arise, and the symptoms produced are very similar. See SULPHONALISM.

HABITS, Personal.—See PERSONAL HEALTH.

HABIT-SPASM.—See OCCUPATION-DISEASES.

HÆMACYTOMETER.—See BLOOD, Examination of (p. 150).

HÆMATEMESIS (αἷμα, blood; and ἔμεω, I vomit).—SYNON.: Fr. *Hématémèse*; Ger. *Blutbrechen*. Vomiting of blood. See HÆMORRHAGE.

HÆMATHIDROSIS (αἷμα, blood; and ἰδρῶς, sweat).—Blood-stained Sweat. See SUDORIPAROUS GLANDS, Disorders of.

HÆMATIN ($C_{76}H_{46}N_4FeO_8$).—Hæmatin may be obtained from red blood-corpuscles by treatment with acids or with strong alkalis.

It is an amorphous dark-brown powder, insoluble in water, alcohol, or ether, but readily soluble in caustic alkalis, in sulphuric or acetic acids, and in chloroform. The acid and alkaline solutions each

give a characteristic spectrum. A solution gives a characteristic absorption-band in the spectrum, different from those produced by hæmoglobin. It forms a green solution when boiled with caustic potash. See SPECTROSCOPE IN MEDICINE.

HÆMATINURIA.—See HEMOGLOBINURIA.

HÆMATOBIUM (αἷμα, blood; βίος, life).—Living in the blood. See ENTOZOA; and MALARIA.

HÆMATOCELE (αἷμα, blood; and κήλη, a tumour).—SYNON.: Fr. *Hématocèle*; Ger. *Blutgeschwulst*.

DEFINITION.—A swelling occasioned by effusion of blood into the sac of the tunica vaginalis, or into a cyst connected with the testicle.

ÆTIOLOGY AND SYMPTOMS.—The extravasation of blood in hæmatocele may take place in a healthy state of the parts, or it may succeed or be combined with hydrocele. In both cases it may be occasioned by a blow, or by violent efforts made in straining, especially in old persons, or when the blood-vessels are diseased. It may happen also from the accidental wound of a vessel in tapping a hydrocele; or, without any such wound, a hæmatocele may supervene if the walls of the sac are very vascular, and a vessel, lacking the pressure of the hydrocele-fluid, gives way. The blood effused, if small in quantity, mixes with the fluid of the hydrocele, and occasions slight enlargement without disturbance. If it be large in quantity, coagula are formed; inflammation is excited in the tunica vaginalis; and plastic exudation occurs on its inner surface, sometimes forming layers, and rendering the sac extremely dense and firm.

The testicle preserves the same relation to the remainder of the tumour as in hydrocele, being situated at its posterior part. Its position, however, is liable to the same alterations which occur in hydrocele, but they are very difficult of detection, owing to the great thickening of the parts.

DIAGNOSIS.—A hæmatocele may be distinguished from a hydrocele by the absence of transparency; the obscure character of the fluctuation; the heavy feel of the tumour when balanced in the hand; the sudden and accidental mode of its occurrence, and the discolouration of the scrotum by infiltration with blood. In old chronic cases in which the tunica vaginalis and its envelopes have become much thickened and indurated, the tumour possesses so firm a character, and feels so heavy and solid, that it is very liable to be mistaken for a chronic enlargement of the testicle; and, more especially, for a malignant tumour, with which it is sometimes associated. The diagnosis is at all times difficult, and in some instances cannot be satisfactorily made out by the most experienced hands until an incision has been made. The records of surgery furnish many cases in which castration has been performed owing to a mistaken diagnosis. In all doubtful cases a trocar should be introduced, or, better still, an incision should be made before any serious operation, such as castration, is undertaken.

TREATMENT.—When a hæmatocele succeeds a hydrocele, the tinged fluid may be removed by tapping, but a radical cure of the hydrocele is now so easily effected, that few patients decline the slight risk the operation involves (see HYDROCELE). Even when inflammation arises, if the sac be tapped

and tension removed, and the patient be kept at rest, with ice applied to the part, the inflammation may subside. When, however, the blood effused is large in quantity, and when the inflammation is acute and threatens suppuration, the tumour should at once be freely laid open by incision, its contents evacuated, and the tunica vaginalis reflexa cut away. This must be done with care, so as to avoid wounding the testicle. Chronic hæmatocele with a very thickened sac must be treated in the same way. The practitioner must bear in mind that the testicle is sometimes situated in front, as in cases of inversion, and is then very liable to injury in the operation of incision, and even in tapping.

Encysted Hæmatocele.—Encysted hæmatocele implies an effusion of blood in the sac of an encysted hydrocele. The treatment is the same as that required for ordinary hæmatocele.

Hæmatocele of the Cord.—Blood may also be effused into the areolar tissue of the spermatic cord, constituting *diffused* hæmatocele of the cord; or into a cyst in the cord, constituting *encysted* hæmatocele of the cord. Such cases are very rare.

In diffused hæmatocele of the cord which persists or threatens to suppurate, incision and drainage may be required. An encysted hæmatocele should be dissected out and, if necessary, the inguinal canal repaired with buried sutures.

T. B. CURLING. C. B. LOCKWOOD.

HÆMATOCELE, Parenchymatous.—This term has been used to designate an effusion of blood into the testicular substance. It is nearly always caused by an injury, and is attended by acute pain. The withdrawal of the blood by means of an aspirator, or trocar and cannula, gives relief. The blood-extravasation may also take place into the epididymis.

C. B. LOCKWOOD.

HÆMATOCELE, Pelvic.—See PELVIC HÆMORRHAGE.

HÆMATO-CHYLURIA.—See FILARIASIS, p. 544.

HÆMATOCOLPOS.—See PELVIC HÆMORRHAGE.

HÆMATOIDIN.—This substance is one of the forms of iron-free hæmatin: it occurs naturally as rhombic prisms or needles of a red or greenish-red colour—a fact which shows that the colour of hæmoglobin is not dependent on the iron. It is of considerable pathological interest, being frequently found in old clots, and in the cavities of ruptured Graafian follicles. It is the cause also of the staining so often seen in the neighbourhood of extravasations of blood, varying from lemon-yellow to reddish-black.

HÆMATOMA (αἱματώω, I fill with blood).—A collection of extravasated blood forming a definite swelling. The contained blood may have undergone certain changes. See CEPHALHÆMATOMA; HÆMATOMA AURIS; PELVIC HÆMORRHAGE; and TUMOURS.

HÆMATOMA AURIS (αἱματώω, I fill with blood; auris, of the ear).—SYNON.: The Insane Ear; Fr. *Othématome*; *Hématome de l'Oreille des Aliénés*; Ger. *Othämatoma*; *Ohrblutgeschwulst von Geisteskranken*.

DEFINITION.—An affection of the auricle,

which occurs almost if not quite exclusively in the insane, and consists in the effusion of blood or bloody serum between the cartilage and its perichondrium, to such an extent as to form a distinct tumour.

ÆTIOLOGY.—In most of the few cases of hæmatoma auris which have been published to show that this disease may occur in the sane, the description given of the patients rather points to their insanity than otherwise. It is most common in cases of general paralysis and mania (acute and chronic), but also occurs in melancholia, dementia, and idiocy. It is about four times as frequent in men as in women; and more often affects the left ear than the right. Sometimes both ears are affected, but seldom at the same time. There would seem to be, in many or all of the insane, a morbid condition of the vessels or other tissues of the auricle, which predisposes to the occurrence of hæmatoma. If this condition be present to a sufficient degree, the disease may arise spontaneously; in other cases a very slight injury may be sufficient to cause it; while in others very considerable violence is necessary for its production.

SYMPTOMS AND COURSE.—The disease first makes itself evident by the appearance of a swelling of about the size of a horse-bean; this is almost always upon the anterior surface of the pinna, and usually in the neighbourhood of the fossa of the antihelix. The skin over the tumour is generally of a reddish or bluish-red colour, but may be unaltered at first; the temperature of the ear is sensibly raised; the swelling is very painful and tender; there is no extravasation of blood from the cutaneous vessels; and the tumour is not œdematous. At this stage, the effusion which has taken place between the cartilage and its perichondrium consists of dark-red fluid blood. In rare cases the swelling does not increase further; the inflammatory symptoms subside after about a week; absorption gradually takes place; and only a slight thickening remains. More usually the tumour increases and may attain the size of a hen's egg; it becomes tense, elastic, distinctly fluctuating, and is often hot and of a bright red colour. Its prominent anterior wall, consisting of skin, cellular tissue, and perichondrium, is felt to be thinner and less resisting than the posterior, which contains the ear-cartilage. In certain cases, however, owing to the brittle cartilage having split up and portions of it having adhered to either wall, both walls present irregularly alternating characters. The time which hæmatoma takes to attain its largest size varies from a week to a month; it then generally involves the whole of the concha, occluding the external auditory meatus; the folds of the auricle are lost, with the exception of the helix (which appears as a band running round the tumour) and the dependent lobule. The weight of the tumour causes the whole ear to fall somewhat forwards and outwards. Sometimes, especially in the presence of constant or repeated irritation, the inflammatory stage may last many weeks, and the deformity which always results from the affection is thereby greatly increased. Unless subjected to violence, it very rarely happens that the tumour opens spontaneously, although its tense and inflamed appearance often seems to indicate that such an occurrence is imminent. If rupture does take place, suppuration ensues; portions of cartilage come away; the cavity closes very slowly; and

great deformity results. The most common course is for the inflammatory symptoms gradually to subside. The anterior wall becomes firmer owing to a new deposit of cartilage upon its inner surface; the sense of fluctuation is gradually lost; and the tumour slowly diminishes in size, often yielding a somewhat doughy sensation to the touch. Occasionally, at this stage, some gaseous contents have been observed in the cavity. The colour of the skin over the tumour becomes gradually more dusky; it then passes into yellow and, later on, into an unnatural pallor. As the fluid contents become absorbed, the tumour becomes harder and smaller; folds again appear in the auricle, but do not correspond to the original ones; and the pinna remains permanently thickened, puckered, and often nodular.

ANATOMICAL CHARACTERS.—Many of these have been given above in explanation of symptoms, and do not require to be repeated. A shrivelled auricle, which has previously been affected by hæmatoma, presents, on section, two distinct layers of cartilage: these are of varying thickness, and separated from each other by vascular fibrous tissue, which often contains within it other small isolated plates of cartilage and sometimes also small portions of bone. The two layers of cartilage have been developed upon the inner surfaces of the perichondrium. The loose portions of cartilage and bone which are occasionally seen are developed from the fibrous tissue. It used to be supposed that the bone (which is soft, vascular, and contains well-developed Haversian systems) resulted from ossification of the ear-cartilage; but the writer has shown that this is not the case.

PROGNOSIS.—The local affection is in no way dangerous, but it always leaves behind it a permanent characteristic deformity of the auricle. The sense of hearing is only affected by the occlusion of the auditory meatus; but this condition very rarely persists after the acute stage. The occurrence of hæmatoma auris influences the prognosis of the mental disease unfavourably, but does not necessarily indicate the approach of a fatal termination to the case.

TREATMENT.—Protection of the part from injury is usually all that is necessary. Cooling applications are useful when the inflammation is excessive. The tumour should not be opened; nor should a portion of the anterior wall be removed, as has been recommended; these procedures almost certainly lead to suppuration, owing to the extreme difficulty of keeping the wound aseptic in an insane patient. It is useless to empty the cavity by aspiration, as it fills again with great rapidity. Treatment by pressure is so painful that the patient will not submit to it.

C. SPENCER COBBOLD.

HÆMATOMETRA.—See PELVIC HÆMORRHAGE.

HÆMATOMYELIA.—Hæmorrhage into the spinal cord. See SPINAL CORD, Diseases of.

HÆMATO-MYELO-PORUS.—A form of hæmorrhage into the spinal cord described by van Gieson. See SPINAL CORD, Diseases of.

HÆMATOPORPHYRINURIA.—Hæmatoporphyrin ($C_{16}H_{18}N_2O_3$) is an iron-free derivative of

hæmatin, isomeric with bilirubin. It is present in minute amount in normal urine, and in larger, but still small, quantities in many morbid urines, which nevertheless show no striking peculiarity of tint. In the condition usually known as hæmatoporphyrinuria, the urine contains this pigment in considerably larger amount and has a dark portwine colour. This colour is only in very small measure due to the hæmatoporphyrin present, and mainly to other abnormal pigments of which very little is as yet known. The condition usually forms one of a group of toxic symptoms, which follow the taking of sulphonal, or even trional, for longer or shorter periods. Occasionally, but rarely, similar urine is passed by patients who have not taken these drugs.

In normal and even in ordinary morbid urines it is seldom possible to detect hæmatoporphyrin without the employment of one of the several methods of extraction, but in the dark red urines some of the bands of the so-called 'alkaline' spectrum or of the 'metallic' spectrum can usually be more or less clearly seen on direct spectroscopic examination. Only when a mineral acid is added does the 'acid' spectrum appear.—See SPECTROSCOPE IN MEDICINE: Coloured plate.

The occurrence of hæmatoporphyrinuria in patients taking sulphonal is of serious import, and calls for the immediate discontinuance of the drug. The administration of alkalis in such cases has been recommended, and should be tried. In cases in which no sulphonal has been taken hæmatoporphyrinuria is not usually a grave symptom.

A. E. GARROD.

HÆMATORRHACHIS.—Hæmorrhage into the spinal canal on either side of the dura mater. See MENINGES, SPINAL.

HÆMATOSALPINX.—See PELVIC HÆMORRHAGE.

HÆMATOTHORAX (αἷμα, blood; and θώραξ, the chest).—An extravasation of blood into the pleural cavity. See PLEURA, Diseases of.

HÆMATOZOA (αἷμα, blood; and ζῶον, an animal).—This term is applied to all kinds of animal parasites dwelling in the blood and blood-vessels. See ENTOZOA; FILARIASIS; MALARIAL DISEASE.

HÆMATURIA (αἷμα, blood; and, οὔρον, urine). SYNON.: Fr. *Hématurie*; Ger. *Blutharnen*. Blood in the urine. See HÆMORRHAGE.

HÆMIC MURMUR.—A murmur connected with an abnormal condition of the blood, as in anæmia. See ANÆMIA; HEART, FUNCTIONAL DISEASES OF; and PHYSICAL EXAMINATION.

HÆMIN (C₂₂H₃₀N₄FeO₄HCl).—Hæmin, which may be prepared from dried hæmoglobin by treatment with glacial acetic acid, in the presence of an alkaline chloride, is a hydrochloride of hæmatin. It crystallises tolerably readily in needle-shaped prisms or rhombic plates, and thus becomes an easy means of detecting the presence of blood in stains of a doubtful nature. The crystals are insoluble in water, alcohol, chloroform, and ether, and soluble in caustic alkalis and boiling hydrochloric and acetic acids. See HÆMORRHAGE (Hæmaturia).

HÆMOCYTOMETER.—See BLOOD, Examination of, p. 150.

HÆMOGLOBIN (αἷμα, blood; and *globus*, a ball).—The colouring matter of the blood. See HÆMATIN; HÆMATOIDIN; HÆMATOPORPHYRINURIA; HÆMIN; and HÆMOSIDERIN.

HÆMOGLOBINOMETER.—See BLOOD, Examination of, p. 152.

HÆMOGLOBINURIA (Hæmoglobin; and οὔρον, the urine).—SYNON.: Hæmatinuria.

DEFINITION.—A morbid condition of the urine resulting from disintegration of blood-corpuscles, characterised by change of colour of the excretion, in consequence of the presence of hæmoglobin and débris of red corpuscles; sometimes paroxysmal; sometimes a result of the action of poisons; and sometimes associated with other more dangerous symptoms, and tending to a fatal result.

ÆTIOLOGY.—Hæmoglobinuria is not referable to any structural change in the kidneys. It is a result of morbid action in the blood, consisting essentially in the disintegration of the red corpuscles whereby the hæmoglobin is set free. It has been observed in the course of fevers, particularly ague and scarlatina, also as a result of insolation, and, in the paroxysmal cases, as a result of exposure to cold, and occasionally after muscular exertion. Hæmoglobinuria has also been described as a conspicuous symptom of a disease attacking newly born infants. In the outbreak described by Winckel of Dresden, in 1879, twenty-three cases occurred in quick succession, and of these nineteen proved fatal. This was evidently due to the action of a specific poison existing in the Maternity Hospital at the time. Cohnheim also showed that hæmoglobinuria may occur as a result of severe, but not speedily fatal, burns. Transfusion of the blood of one kind of animal into the veins of another suffices to produce it. Moreover, many poisons have been found to induce the condition. By far the most important of these is chlorate of potassium. In the case of children, one to two drachms in the twenty-four hours is a dangerous quantity; in the adult, three drachms or upwards. Next to it, but at a long interval, rank carbolic, hydrochloric, sulphuric, and pyrogallic acids, and the inhalation of arseniuretted hydrogen gas. In what way we are to explain the action of these various substances upon the blood-discs is as yet far from clear, but the fact that they do so act is fully established.

MORBID ANATOMY.—The kidneys are of a deep chocolate colour throughout, with radiating striae of a darker tint. The sections show under a low power dark lines corresponding to the tubules, and spots marking the Malpighian bodies. With a higher power one makes out that the tubules are blocked with granular pigment, and that this is discharge from the Malpighian tufts. There are sometimes alterations in the spleen and in the bones, and hæmorrhages into various tissues.

SYMPTOMS.—The chief clinical features of hæmoglobinuria are those referable to the urine. It is dark like porter, or like the sediment of port wine; sometimes brown like coffee, or almost black. This colour is due mainly to blood-pigment, and usually few, if any, blood-corpuscles are present. Pigmented tube-casts and oxalate-of-lime crystals are often present in large numbers. The urine yields

a coagulum on heating, or on the addition of nitric acid. Examined spectroscopically, it shows the characteristic absorption-bands of oxyhæmoglobin and methæmoglobin. Otherwise the patient shows tokens of general discomfort : gastro-intestinal disturbance ; jaundice more or less pronounced ; sometimes enlargement of the spleen, and subcutaneous hæmorrhages ; weakness of the heart ; and tendency to hypostatic congestion in cases of a bad type, with other symptoms of depression or even collapse.

DIAGNOSIS.—The different forms of hæmoglobinuria have to be diagnosed from each other, and from certain diseases which resemble the paroxysmal forms. See HÆMOGLOBINURIA, PAROXYSMAL ; and BLACKWATER FEVER.

PROGNOSIS.—Cases of this kind rarely terminate unfavourably except when hæmoglobinuria is merely one of many symptoms in connection with blood-poisoning.

A. E. GARROD.

HÆMOGLOBINURIA, PAROXYSMAL. —

SYNON. : Paroxysmal Hæmatinuria.

DEFINITION.—A paroxysmal affection of the system ; manifesting itself by changes in the urine, and particularly the discharge of hæmoglobin ; caused sometimes by syphilis or malaria, and sometimes by other conditions not yet determined ; unassociated with any anatomical change as yet recognised ; and characterised by the occasional occurrence of constitutional disturbance, with discharge of dark, blood-stained urine.

ÆTIOLOGY.—The more recent researches point to syphilis as the most important of the extrinsic causes of the disease, and assign to malaria a less important share in its causation than it was at one time supposed to have. By far the most important cause of the paroxysm is exposure to cold : in a few instances the attacks have followed exertion. Among intrinsic causes, sex is evidently important, for the disease is almost confined to males. It may occur in children, and is apt to persist during a period of years.

As in other forms of hæmoglobinuria, the symptom is traceable to disintegration of red corpuscles within the circulating fluid, but the manner in which this is brought about still remains very obscure. That such disintegration may occur locally has been proved experimentally by Ehrlich. He tied a ligature round the finger of a patient who was liable to the disease, and then chilled the congested part by immersing it for a quarter of an hour in ice-cold water, afterwards transferring it for a like period to tepid water. In this patient it was found that many corpuscles were broken down, while no such effect was produced elsewhere in the body or in healthy people. Chvostek has shown that the ligature alone suffices to bring about this result, and also that cold alone does not cause an undue hæmolysis in the blood of such patients outside the body. On the other hand their blood is disintegrated with undue ease by mechanical influences such as shaking in a test-tube and also by the action of carbon dioxide. Murri and others regard the vaso-motor disturbances which accompany the attack as playing an equally important part with the abnormal blood-condition in causing the hæmoglobinuria.

The attack is attended by a conspicuous fall in the number of red corpuscles, but the loss is quickly repaired. The morphological blood-changes are not very characteristic ; there is an absence of the

tendency to rouleaux-formation, and some observers lay stress upon the presence of decolourised red corpuscles (*Blutschatten*) which they regard as a characteristic feature. During the attack the serum contains free hæmoglobin and may have a pink tint. The few recorded *post-mortem* examinations have not revealed any very striking changes, but the presence of some interstitial change in the kidneys suggests that the undue calls upon these organs during the paroxysms may not be quite free from ill effects upon them.

SYMPTOMS.—This form of hæmoglobinuria is paroxysmal, but not periodic. It may commence in childhood or during adult life. The recurrence of the attacks is determined by exposure to the exciting cause. The paroxysm may commence abruptly without any premonitory symptom, but is more commonly ushered in by a feeling of uneasiness in the loins and limbs, by shivering, and general chilliness. Sometimes it is preceded by furred tongue, and other symptoms of gastric catarrh ; and sometimes albuminuria precedes by a few hours the occurrence of hæmoglobinuria. Some degree of vaso-motor disturbance, evidenced by coldness of the extremities and often by 'deadness' and pallor of the fingers, usually accompanies the paroxysm, and the attack may be followed by a slight degree of jaundice. The more abrupt attacks frequently terminate by the discharge of the peculiar urine, the uneasy feelings having subsided before it occurs ; and the next urine is normal, or nearly so. In some cases albuminuria precedes or lingers for a time after the discolouration has passed off, and sometimes it replaces the hæmoglobinuria. After an initial fall during the exposure the temperature rapidly rises to 101° or 103° F. and as rapidly falls to normal again when the attack subsides.

The characters of the urine are very peculiar. Its colour is like porter, or like that of muddy port-wine ; its specific gravity ranges from 1015 to 1035 ; it is acid, or faintly alkaline ; it is highly albuminous ; sometimes it contains excess of urea. It throws down a copious sediment, which contains very few or no blood-corpuscles, but an immense amount of granular blood-pigment, with numerous tube-casts—hyaline or epithelial, often loaded or coated with amorphous granular matter, and with minute crystals of oxalate of lime. The colour is not due to blood-corpuscles, nor to hæmatin, but as a rule to a mixture of oxy- and methæmoglobin. The absorption-band in red of methæmoglobin is usually clearly visible when the urine is examined with the spectroscope (see SPECTROSCOPE IN MEDICINE: Coloured plate). In some cases the urine is less affected, being merely albuminous, and not depositing pigment.

A very interesting point in the clinical history of hæmoglobinuria is its relationship to Raynaud's disease. The relationship is neither constant nor exclusive, and the precise link which connects them is as yet not clearly determined. Still the clinical fact remains, that when the one disease exists the other is not infrequently present, and, as has been already mentioned, some vaso-motor spasm is present during most paroxysms of hæmoglobinuria.

DIAGNOSIS.—The only diseases with which intermittent hæmoglobinuria is likely to be confounded are hæmaturia, and renal calculus or gravel. From the former it is distinguished by the abundance of the blood-pigment and the extreme rarity of blood-

corpuscles; from the latter, by the short duration of the attacks, the presence of the characteristic deposit, with the fact that the pains affect both loins, not merely one. It is sometimes important to distinguish the milder forms, in which merely albuminuria occurs, from congestion or from commencing inflammatory Bright's disease. It is not always possible to distinguish these during the early hours of the attack; but the amount of general disturbance, the state of the tongue, the slight jaundice, the suddenness of the onset, and the absence of dropsy, generally suffice to make the diagnosis clear.

PROGNOSIS.—The prognosis is good in paroxysmal hæmoglobinuria, as to the individual paroxysm. The tendency to the disease is also not infrequently got rid of. It has not proved fatal in any case.

TREATMENT.—With a view to preventing the attacks, individuals who are subject to paroxysmal hæmoglobinuria should carefully avoid exposure to cold and over-fatigue of every kind. They should take abundance of good and easily digested food, should avoid free use of alcohol, and should clothe warmly. As the paroxysm is spontaneously recovered from, little need be done, excepting with the view of alleviating the discomfort of the patient. Chvostek found that nitrite of amyl administered at an early stage tended to cut short or avert the paroxysm, but Mannaberg and Donath failed to obtain this result. The patient should go to bed and be kept warm, and have abundance of warm drinks. In respect of diminishing or removing the tendency to the malady, various remedies have been found useful, among which may be mentioned quinine, tincture of cinchona, iron, arsenic, and chloride of ammonium. Antisyphilitic treatment by means of mercury has also been found useful, and has even brought about a cure in some cases.

HÆMOGLOBINURIC FEVER.—See BLACK-WATER FEVER.

HÆMO-PERICARDIUM (αἷμα, blood; περί, about; and καρδιά, the heart).—An extravasation of blood into the sac of the pericardium. See PERICARDIUM, Diseases of.

HÆMOPHILIA (αἷμα, blood; and φίλος, predisposition for).—SYNON.: Hæmorrhagic Diathesis; Bleeders; Fr. *Hémophilie*; Ger. *Bluterkrankheit*.

DEFINITION.—A congenital disease, often hereditary, characterised by a tendency to immoderate bleedings, whether spontaneous or traumatic, and to obstinate swellings of the joints.

ÆTIOLOGY.—Men are far more liable than women to this disease, the proportion being about eleven to one. Women who suffer from hæmophilia show much less typical specimens of the disease than men, and rarely die from hæmorrhage, although floodings and profuse menstruation are common.

The best-ascertained cause of hæmophilia is hereditary predisposition. No other cause is known with anything like certainty. The origin of the disease *de novo* has not been definitely proved. In a family of bleeders, the disease descends as a rule to the boys through the mothers, the women remaining quite healthy and apparently free from all disease. In this way it may persist through seven generations,

as in the Appleton-Swayne family. The fathers do not seem to transmit the disease to their sons: at least, instances of this are rare. The women of bleeder families are remarkably fertile. Some have thought hæmophilia to be more common in Germany, but this is probably owing to the greater attention paid to the disease in that country. Cases have been met with in the Indian Archipelago, North America, the Scandinavian kingdoms, and elsewhere. The disease is not limited to the Aryan races, as the Jews, a Semitic people, are singularly liable to it.

ANATOMICAL CHARACTERS.—No morbid appearances have yet been found after death with any constancy. The blood-vessels are apparently unaltered. The condition of the blood has not yet been properly investigated. The statement that the blood-platelets are diminished in number or altogether absent also lacks confirmation. It has been suggested that there is a marked increase in the mass of the blood, and it has been repeatedly found that there is an increase in the number of red blood-corpuscles. It would be important to ascertain whether the number of white corpuscles is increased or diminished, and whether they are altered in character. The swellings of the joints appear in some cases to be due to the extravasation of blood within the articulation. At other times it may apparently represent an irritation of the bone-marrow.

SYMPTOMS.—The first signs of hæmophilia are commonly seen during the first year of life; but sometimes they are delayed until the beginning of the second dentition. Cases on record of a much later appearance of the first symptoms are not trustworthy. It is very rare for bleedings to be noticed at birth. There is nothing about the subjects of hæmophilia, when not suffering from bleeding, to distinguish them from ordinary persons. They look well; and nothing amiss can be discovered by physical examination in the chest or abdomen.

There are three well-marked *degrees* of hæmophilia. The first is the most typical and characteristic, in which there is a tendency to every kind of hæmorrhage, traumatic or spontaneous, interstitial or superficial. The swelling of the joints is well-marked. This degree is scarcely ever seen in women; but it is the most common among men. In the second degree, spontaneous hæmorrhages from the mucous membranes only are present. The third degree, in which the tendency is little marked, is seen only among the women of bleeder families; and shows itself only by spontaneous ecchymoses.

Hæmorrhage.—Spontaneous bleedings are sometimes preceded by symptoms of unusual fulness and plethora. The mucous membranes supply the blood in this case; in childhood bleeding from the nose is the most common, and also the most fatal, although bleedings from the bowel, mouth, or chest may also occur. There has been only one known instance of death from hæmaturia. The traumatic bleedings vary much in intensity, even in the same individual. Death has followed division of the frenum of the tongue, vaccination, leeching, and the extraction of a tooth. This last is a very common cause of death. If abscesses be opened, furious bleeding commonly takes place; and the same occurs if a blood-tumour or extravasation of blood be interfered with.

The bleeding is nearly always capillary, and may kill in a few hours or after some weeks. The

quantity of blood lost is sometimes enormous. After the bleeding the patients are extremely anæmic; and this state may last for months.

Besides superficial bleedings, interstitial hæmorrhages, ecchymoses, and blood-tumours may be observed, whether spontaneous or traumatic. A bruise which a healthy person would not feel may fill the connective tissue of a limb with blood; or the bleeding may be circumscribed, and form a tumour instead.

Swelling of the joints.—This chiefly affects the larger joints, the knee being most commonly attacked. The pain may pass from one joint to another and finally settle in the knee. The joint, most commonly after some injury, becomes swollen and painful, and apparently filled with fluid; there is fever; and this state may last for many weeks. Relapses are very apt to occur during convalescence.

A case of hæmophilia of one kidney has been reported, and the removal of the affected organ led to cure (Senator). As a rule the disease lasts throughout life, but may become less marked with advancing years. Some bleeders may reach old age and ultimately die of disease unconnected with their hæmorrhagic diathesis.

DIAGNOSIS.—The diagnosis of hæmophilia is often easy. If from early infancy a boy have suffered repeatedly from abundant bleeding—especially traumatic—and from joint-affections, there can be no doubt of the diagnosis. It is made more certain by the existence of hereditary predisposition. In women the diagnosis must be made with more care, as they are subject to hæmorrhagic disorder which first appears about puberty, but which is not hereditary. See MENSES, Disorders of.

PROGNOSIS.—The prognosis is not so serious with respect to life as was formerly thought.

TREATMENT.—The treatment of hæmophilia includes almost the whole subject of the treatment of hæmorrhage. Surgical interference in the way of the ligature of arteries is, however, contra-indicated in connection with hæmophilia, as the hæmorrhage in such cases is almost exclusively capillary. For the same reason, the administration of ergot, with a view to bringing about a contraction of the arterioles, would not be likely to prove of service. Treatment ought to be directed entirely to bringing about an increase (*a*) in the rapidity of coagulation, and (*b*) in the firmness of the resulting clot. In our present ignorance on the subject of the pathology of hæmophilia, treatment must take cognisance of every factor which is known to influence the coagulability of the blood. The facts that have been ascertained in connection with this subject are as follows: A defect in coagulability may depend on one or other of the following conditions:—

A Defect in the Inorganic Substratum of Fibrin.—This may consist in a diminution of the amount of available calcium-salts in the blood. Defective coagulation arising from this cause is to be met by the administration of lime-salts, preferably calcium chloride (grs. x–xx). Owing to the disagreeable taste and deliquescent nature of the salt, it is best administered in the form of a varnished pill or an enema. A one-per-cent. solution of calcium chloride may also be applied as a local styptic. Stronger solutions are not to be recommended, as coagulation is retarded after a certain percentage of calcium has been exceeded. In view of the fact that the action of the lime-salt is not instantaneous, the solution must be applied on a tampon

in such a manner as to hinder the flowing away of the blood with which it comes in contact. In all cases the clots obtained by the addition of lime to the blood are characterised by an extraordinary firmness. The coagulative efficacy of a solution of lime-salts can be increased by the addition of fibrin-ferment. This last can be obtained by extracting washed fibrin with water.

A Defect in the Organic Substratum of Fibrin.—There is little doubt that the coagulation of the blood is brought about by the combination of an element of plasma-fibrinogen with a fibrinoplastic element derived from the breaking down of the white corpuscles. This fibrinoplastic element consists of the substance which is known as Woolridge's tissue- or cell-fibrinogen. A diminution of the available tissue-fibrinogen in the blood leads to a condition of diminished coagulability. Its addition to the blood in all cases is followed by an immediate increase of coagulability, and an increased formation of fibrin. In view of this fact a local application of tissue-fibrinogen would appear to be indicated when hæmorrhage in hæmophilia does not yield to the application of lime, or lime and fibrin-ferment. Tissue-fibrinogen may be obtained in the following manner: Procure the thymus gland (the chest-sweetbread) or testicle of a calf, lamb, or other animal. Mince it fine in a mincing-machine, and extract with, say, twenty times its volume of water for ten minutes to twenty-four hours. Strain through fine muslin or through flannel, and add to each pint of the strained infusion 1 ounce of diluted or 1 fluid drachm of strong acetic acid (B.P.). A precipitate of tissue-fibrinogen forms almost immediately. Allow it to settle, and get rid of the supernatant fluid by decantation, or, better, collect the precipitate on a filter-paper. In either case dissolve the tissue-fibrinogen thus obtained by the addition of a few drops of alkali (dilute carbonate or bicarbonate of sodium). Apply the somewhat viscid solution on a tampon of cotton-wool to the bleeding point. Escharotics such as ferric chloride are seldom found to be of any service in bleeding in hæmophilia.

In cases of severe hæmorrhage, transfusion may be necessary. See SALINE SOLUTION, INFUSION OF; and TRANSFUSION.

GENERAL TREATMENT OF THE MORBID CONDITION.—It is impossible in our present ignorance of the pathology of hæmophilia to lay down a scientific method of treatment. It will, however, be evident that any treatment directed towards rendering the blood more coagulable would be indicated. Thus the administration of lime-salts might prove useful. Further, the means which are at our disposal for increasing the number of white corpuscles in the blood might be employed, with a view of increasing the amount of the fibrinoplastic element, for we have seen that tissue- or cell-fibrinogen is contained in the white corpuscles. While awaiting further information on this subject, the following therapeutic agents might be brought into requisition: (*a*) The administration of aromatic substances, such as camphor and turpentine. The administration of these substances increases the number of white corpuscles in the blood (Binz), and they are employed apparently with success in the treatment of internal hæmorrhages. (*b*) The administration of pilocarpine (Horbaczewski), which increases the number of circulating white corpuscles. (*c*) The administration of nuclein (Horbaczewski),

or nuclein-containing substances such as tissue-fibrinogen (Wright), for these substances increase the number of white corpuscles in the blood. They are available in the form of yeast, sweetbreads, lamb's fry, and kidneys. It has, however, not yet been ascertained whether these cell-substances lose their efficacy on boiling. The subcutaneous inoculation of 100–200 cubic centimetres of a sterilised 1–2½-per-cent. solution of gelatine (of the quality used for bacteriological purposes) has recently been favourably reported on.

A. E. WRIGHT.
WILLIAM BULLOCH.

HÆMOPTYSIS (αἷμα, blood; and πτύω, I spit).—SYNON.: Fr. *Hémoptysie*; Ger. *Bluthusten*. Hæmorrhage from the larynx, trachea or lungs. See HÆMORRHAGE.

HÆMORRHAGE (αἷμα, blood; and ῥήγνυμι, I burst forth).—SYNON.: Fr. *Hémorrhagie*; Ger. *Blutfluss*.

DEFINITION.—The escape of blood from any part usually containing it.

This article will deal generally with those cases of hæmorrhage which result in the expulsion of blood from one of the natural passages opening on the outside of the body, viz. (1) Nose (see EPISTAXIS), (2) Mouth (Hæmoptysis and Hæmatemesis), (3) Ear (Otorrhagia), (4) Anus (see INTESTINES, HÆMORRHAGE from; and MELÆNA), (5) Urethra (Hæmaturia), (6) Vagina (see METRORRHAGIA). Hæmoptysis, Hæmatemesis, and Hæmaturia are considered in detail at the end of the present article.

ÆTIOLOGY.—The causes of hæmorrhage thus defined may be placed in three groups.—1. *General causes.*—a. Uniformly distributed disease of the vessels or defects in the composition of the blood may lead to hæmorrhage. This group includes *leucocythemia*, *pernicious anemia*, *hemophilia*, *scurvy*, and *purpura*. These diseases may give rise to hæmorrhage from any of the sites just mentioned. To these may be added *yellow fever* and *acute yellow atrophy of the liver*, which may cause hæmorrhage into the cavity of the stomach and consequently hæmatemesis.

b. Sudden and extreme increase in the venous pressure may cause rupture of indifferently supported vessels. In this way epistaxis or otorrhagia may be caused by a paroxysm of *whooping cough*.

2. *Local causes.*—a. Injury of the vessel or vessels from which the hæmorrhage occurs is often the responsible cause. Thus, a *broken rib* may give rise to hæmoptysis from damage to the vessels of the subjacent lung; a *calculus* in the pelvis of the kidney may cause hæmaturia; and a *swallowed fish-bone* or *corrosive poison* may produce hæmatemesis.

b. Disease of the vessel-wall may so weaken it that it gives way under the ordinary blood-pressure. Among the diseases weakening the walls of the vessels, *tubercular arteritis* stands first as the principal cause of hæmoptysis in phthisis. Necrosis of tissue depending on the direct action of other bacterial products, or on vascular occlusion—conditions occurring in *suppuration*, *syphilis*, and *enteric fever*—may also lead to destruction of part of a vessel-wall before the lumen is closed by thrombosis. *Local arterio-sclerosis* may lead to rupture of the aorta, and the invasion of the lung by a *new-growth* may cause hæmoptysis from rupture of the vessels of the

tumour. c. Increased local intra-vascular pressure may lead to the rupture of the affected vessel. Thus, the increased pressure in the portal vein in cases of portal *cirrhosis* of the liver may cause copious hæmorrhage from œsophageal varices, themselves a result of the earlier stages of the disease, and so give rise to hæmatemesis. The engorgement of the pulmonary vessels in *mitral stenosis* is frequently attended by hæmoptysis.

3. *Miscellaneous causes.*—It is necessary to mention the possibilities of *feigned hæmorrhage* as well as the so-called *vicarious hæmorrhage* believed by some to take the place of arrested menstruation. Moreover, blood may be subsequently mixed with a discharge and give rise to erroneous conclusions, as in the case of hæmaturia due to admixture with blood from the vagina. See LIFE ASSURANCE.

CHARACTERS.—The appearance of the blood will vary with the amount and source of the hæmorrhage, with the time which has elapsed since its escape from the vessels, with the place in which it may have been retained, and with the substances intermixed with it. In general terms, blood from an artery is bright, and blood from a vein dark; but this distinction is often of little value, since blood exposed to air will soon become bright red, whatever its source. A copious hæmorrhage from a small aneurysm in a tuberculous lung will present precisely the same appearance as a similar amount of blood from the dilated veins at the lower end of the œsophagus in a case of cirrhosis of the liver. The blood from a small hæmorrhage is more likely to be retained within the cavities of the body, and therefore to show signs of decomposition when expelled. Consequently, large hæmorrhages present the greatest difficulties in diagnosis, so far as the appearance of the blood is concerned; and blood altered so as almost to resemble coffee-grounds is generally derived from some part in which it can be easily retained, and in which chemical changes readily occur, e.g. from the stomach rather than from the lung. For similar reasons a small amount of bright blood passed *per anum* is generally derived from the lower end of the rectum, and a large amount of dark tarry blood from the stomach or duodenum. The substances intermingled with the blood will often afford assistance in the diagnosis of its origin. Recognisable particles of food are generally derived from the stomach, though if a meal have been taken a short time previously, a few fragments might have collected in, and be ejected from, the mouth. Bronchitic or phthisical sputa mixed with blood expectorated the day after a hæmorrhage afford certain evidence of its origin.

DIAGNOSIS.—The diagnosis of the exact site of the hæmorrhage depends upon the consideration of four items of evidence. 1. *The history of the patient.*—This may reveal the occurrence of injury or the existence of disease sufficient to give rise to the hæmorrhage. 2. *The phenomena attending the expulsion of the blood.*—Coughing or vomiting will at once suggest the origin of the hæmorrhage, though vomited blood, unless in large quantity, may have been previously swallowed. 3. *The characters of the blood.*—These have already been considered. 4. *The physical examination of the patient.*—This is only permissible to a very limited extent, but mere observation, palpation, and auscultation may suffice to discover a thoracic aneurysm, a tuberculous lung, or a cirrhotic liver.

EFFECTS.—A small hæmorrhage from the nose,

from the rectum, or even from the lung may be followed by a sense of relief and give rise to no unpleasant effects. The rapid loss of a large quantity of blood is attended by pallor, sudden fall of temperature, collapse, rapid breathing, syncope, and, just before death, convulsions. A second large hæmorrhage within twenty-four hours is generally fatal. At the end of this time regeneration of the blood proceeds rapidly, and the danger, therefore, speedily diminishes. Repeated hæmorrhages may lead to persistent anæmia. See BLOOD, Morbid Conditions of.

If the hæmorrhage depend on any of the general causes, on local increase of the blood-pressure, or on injuries, it will tend to cease gradually as the intravascular pressure diminishes. If, however, it depend on the rupture of a softened part of an arterial wall, or on an ulcerated opening in a vein, it will often increase, continue, or recur at short intervals.

TREATMENT.—Healing takes place primarily by thrombosis, and later on by proliferative inflammation of the affected vessel. To produce this, absolute rest—physical, emotional, and mental—and a low blood-pressure are essential. The faintness following a hæmorrhage is itself beneficial, and stimulants should never be given with a view to removing it, although the patient may thereby be temporarily gratified. The posture to be recommended will vary with the seat of the hæmorrhage, but the administration of morphine is a safe procedure in nearly all cases of severe hæmorrhage. Styptics may be employed if there is any probability of the drug reaching the affected part. Ergot and its derivatives should never be given if the hæmorrhage is due, as it usually is, to diseased vessels or increased intravascular pressure, but may be useful in capillary hæmorrhage or when a muscular organ, like the uterus, is the seat of the hæmorrhage. It is sometimes necessary to adopt measures calculated to increase the coagulability of the blood. See HÆMOPHILIA.

Hæmatemesis.—**SOURCES.**—Vomited blood may be derived from vessels in the œsophagus, stomach, or duodenum; or from the rupture of an aneurysm through the wall of one of these organs.

ÆTIOLOGY. 1. *General.*—Any of the *hæmorrhagic diseases of the blood* enumerated above may give rise to hæmatemesis, copious or slight, but no general increase in the venous pressure, however sudden, is likely to cause it.

2. *Local.*—Injury of the vessels may be due to penetrating *wounds* from the outside or inside (fish-bone), or *corrosive fluids*. Blood derived from these sources is small in amount and dark in colour. *Prolonged retching* may cause rupture of a small vessel and give rise to the vomiting of a small amount of bright blood. An *aneurysm* of the abdominal aorta or of one of its upper branches may occasionally rupture into the stomach, and if this occur the vomited blood will be abundant and bright. Among the diseases of the vessel-walls, *acute ulceration* of stomach or duodenum must be placed first. A branch of the splenic, coronary, or superior pyloric artery may be opened, and the resulting hæmorrhage be proportionately severe; in such case the blood is bright and sometimes frothy. Occasionally in acute ulceration and almost invariably in chronic ulceration or in the ulceration of a *malignant growth* only small vessels are affected

and but little blood is effused, and this is not ejected until it has undergone considerable change and become of coffee-ground appearance. The hæmatemesis so frequently complicating portal cirrhosis of the liver is generally copious, and the blood bright, though derived from the ulceration and rupture of the dilated venous anastomoses at the lower end of the œsophagus, and often passing into the stomach before being expelled from the mouth. If blood, escaping into the œsophagus, either from ruptured varicose veins or from an aneurysm of the descending thoracic aorta, be expelled at once, it is voided easily without cough or vomiting.

3. *Accidental.*—Blood derived from the nose, gums, larynx, lungs, and elsewhere may be swallowed and subsequently vomited. It is then more or less discoloured and rarely exceeds a few ounces.

DIAGNOSIS.—When the blood is much altered by the action of the other gastric contents, the appearance it presents may be closely simulated by food, bile, medicines containing iron, and red wine, if these have been detained in the stomach for a few hours. In doubtful cases a filtered solution of the vomit in caustic potash should be prepared and examined by means of a pocket-spectroscope (see SPECTROSCOPE IN MEDICINE); or the *hæmin-test* may be employed (p. 622). The history of the case and the reddish-brown colour of the vomit are, however, in most cases, a sufficient guide. Cough may accompany hæmatemesis.

PROGNOSIS.—First attacks of hæmatemesis are not generally fatal unless due to rupture of an aneurysm, or to implication of the aorta or of any large arterial trunks supplying the stomach. As the exact local condition in ulceration can never be ascertained no definite prognosis can ever be given. The recurrence of hæmorrhage very seriously affects the prognosis.

TREATMENT.—If the hæmorrhage is severe, half a grain of morphine should be given by hypodermic injection; and absolute rest in the recumbent posture be maintained for six hours, no movement of any kind being permitted. At the end of that time rectal feeding, by suppositories, may be commenced, but nothing, not even ice, must be given by the mouth; although, to allay thirst, the tongue may be painted with lemon-juice and a little glycerine, and a few ounces of warm water may be injected into the rectum. If the collapse is serious, ammonia may be gently sniffed as a stimulant, or half an ounce of brandy given *per rectum*. Styptics are of doubtful benefit. Fifteen-grain doses of gallic acid or 4 grains of the *Pilula Plumbi* c. Opio may be given by the mouth. When the hæmorrhage clearly depends on cirrhosis of the liver, styptics are of most use, while morphine is often unnecessary. In these cases calomel followed by a saline purge should be given after an interval of two days. Cautious feeding by the mouth may be recommenced at the end of three days, except in acute ulceration, when it should be deferred until ten days have elapsed.

Hæmoptysis.—**SOURCES.**—The laryngeal, bronchial, and pulmonary blood-vessels, or an aneurysm bursting into the air-passages from without.

CAUSES.—1. *General.*—Hæmoptysis from blood-diseases is usually slight, the blood being generally derived from the mucous membrane of the larynx, trachea, or bronchial tubes.

2. *Local*.—Blood escaping from the lungs is chiefly due to local changes. *Injury*, such as a broken rib pushed inwards, may damage the vessels of the lung and give rise to hæmoptysis without producing pneumothorax or hæmorthorax. Inhaled foreign bodies, especially if provided with sharp edges or points, may damage the mucous membrane of the air-passages and cause hæmoptysis. An aneurysm of the transverse or descending aorta may burst into the air-passages and cause fatal hæmorrhage, often preceded by slight hæmoptysis for a few days.

Disease of the vessels leading to rupture is usually tubercular. (1) Tubercular arteritis may affect the smaller branches of the bronchial or pulmonary arteries and cause such weakening of the walls that the ordinary pressure, especially during coughing, suffices to cause rupture of the diseased vessel. The lumen of the vessel is often much diminished before rupture occurs, thrombosis readily follows the local fall in blood-pressure, and consequently the hæmorrhage is often slight. This is the chief cause of hæmorrhage in early phthisis. (2) In the necrosis and caseation of tissue which leads to the formation of a tubercular cavity, two changes leading to hæmorrhage may affect the principal vessels traversing the affected area. (a) The cavity may arise in the immediate neighbourhood of an arterial branch of medium size, and the wall may be inflamed and weakened at the outset, dilating under the intra-vascular pressure so as to form an aneurysm, the walls of which are in immediate contact with those of the cavity, which it fills. Sooner or later, as the cavity enlarges, the wall of the aneurysm will give way, and the blood be ultimately discharged through any connection that may exist between the cavity and the air-passages. This is the principal cause of severe hæmoptysis in late phthisis. (b) In a few cases the walls of large arterial trunks traversing a large chronic cavity may undergo ulceration and rupture before their lumen is entirely obliterated. In such cases severe hæmorrhage may follow. Laryngeal hæmorrhage is generally due to ulceration—acute or malignant. In both cases it may be slight or severe. Hæmorrhage is very rare in tubercular ulceration of the larynx. In this group must be placed the hæmoptysis—slight in the early stages, severe and often fatal in the later—of malignant growths arising in or invading the lung; also the hæmorrhage due to the presence of a hydatid cyst, the *Distoma Ringeri*, bronchiectatic ulceration, and gangrene; for although hæmoptysis may be the first sign of gangrene, it generally occurs during the later stages and is then not infrequently fatal.

Increased intra-vascular pressure.—This may co-exist with any of the preceding conditions and facilitate rupture of the affected vessels. In most cases, however, it acts upon vessels uninjured save by the interference with their nutrition dependent upon passive congestion. This is the principal cause of the slight hæmoptysis which may follow severe coughing in bronchitis, and of the attacks of more severe bleeding that rarely complicate asthma; but it is best illustrated by the more copious hæmorrhage liable to occur in mitral stenosis. In this disease the vessels of the lungs are not infrequently permanently over-distended and the circulation slowed, so that thrombosis and infarction are common occurrences (see LUNG, Hæmorrhage into). Local variations in blood-pressure are thus easily induced, rupture of vessels is frequent, and hæmo-

pysis results. In hæmoptysis of moderate severity in young persons the diagnosis generally lies between tubercular arteritis and the increased intra-venous pressure of mitral stenosis.

EFFECTS.—The immediate effects will vary with the extent and recurrence of the hæmorrhage (p. 619). Suffocation may result from hæmorrhage into the air-passages: and even if this be averted inhalation of the blood may be followed by a fatal attack of acute pneumonia, or possibly by a spread of tuberculosis.

DIAGNOSIS and PROGNOSIS.—These depend mainly upon considerations already mentioned (p. 619). The onset of fever in hæmoptysis adds much to the gravity of the prognosis.

TREATMENT.—If the hæmorrhage be small in amount, merely tinging the expectoration, a few days' rest should be enjoined, a light diet be ordered, and a mild aperient be given. As soon as the disease causing the hæmorrhage has been ascertained, measures for its relief must be undertaken. If a tubercular origin be suspected, though without clear evidence, open-air life in a dry sunny climate suited to the taste, physique, and means of the patient should be insisted upon, until, at any rate, the possible development of tubercular changes can be excluded.

If the hæmorrhage be sufficiently severe to give rise to symptoms, the patient must be kept absolutely still in bed with the shoulders well raised, and the body efficiently and comfortably supported. No movement should be permitted, and no conversation allowed. The patient should be reassured, but the visits of friends must be reduced to a minimum. Hot-bottles should be applied to the extremities, and a hypodermic injection of morphine (gr. $\frac{1}{2}$) should be given to aid the completeness of the rest and to prevent cough. A saline aperient should be given. For three to six hours no food should be allowed, although small pieces of ice may be placed in the mouth. Subsequently cold fluid food may be administered in small quantities every two hours. In the large majority of cases this is all the treatment that is necessary or indeed useful. If syncope be feared, the inhalation of ammonia is often beneficial, provided it does not excite cough; stimulants in small quantity may be needed. Styptics are useless, and ergot is harmful as it increases the blood-pressure without contracting the diseased vessel which is too damaged to react to its influence. The inhalation of turpentine and the application of an ice-bag over the chest are procedures sanctioned by usage but of no certain benefit; indeed the ice-bag is probably prejudicial, since it causes contraction of the uninjured parts of the lung. When the danger of recurring hæmorrhage has ceased the secondary anemia and the original disorder must be carefully treated.

Hæmaturia.—The term hæmaturia is used whenever red blood-corpuscles are found in the urine; if only hæmoglobin be present the term is not applicable. See HÆMOGLOBINURIA.

SOURCES.—Blood in the urine may be derived from the kidney or its pelvis, from the ureter, bladder, prostate, or urethra, or, in the case of the female, it may be due to the admixture of blood with the urine after the latter has left the urethra. Blood may also be mixed with the urine fraudulently.

1. *General Causes*.—The hæmorrhagic diseases previously mentioned only rarely cause hæmaturia.

When this does occur the blood is probably derived from the pelvis of the kidney or from the bladder. The toxic or malignant forms of the acute specific fevers may also give rise to a similar condition of the urine.

2. *Local Causes.*—*Renal Hæmaturia.*—When the blood is derived from the kidney it is intimately mixed with the urine. If the hæmorrhage is a large one the resulting blood may be indistinguishable from pure blood; if it is slight a dirty smoky tint is imparted to the urine, and in some instances a reddish-brown precipitate is deposited on standing. Blood-casts are most readily found when the hæmorrhage is slight. (a) Slight transitory renal hæmaturia may follow the administration of cantharides, turpentine, cubebæ, copaiba, potassium nitrate, quinine, phenol, and hydrochloric acid, if these are given in toxic doses. (b) In acute inflammatory diseases of the kidney a moderate amount of blood and numerous blood-casts are generally found at some stage of the disease. When the acute condition supervenes upon chronic Bright's disease other forms of casts will be found. (c) In cases of renal tumour and of tumour or calculus in the pelvis of the kidney, ruptured vessels may cause large amounts of blood to appear at irregular intervals, especially after slight injury. (d) In renal embolism sudden hæmaturia is common, but the quantity of blood is small and the condition soon disappears. (e) In renal tuberculosis there may be sufficient blood to produce smoky urine, but in the majority of cases it exists only as a microscopical deposit. (f) Parasites, such as the cystic stage of the *Tænia echinococcus* (hydatid), hydronephrosis, and traumatism are occasionally causes of renal hæmaturia. (g) Passive congestion from pressure on the renal veins is a rare but possible cause of hæmaturia.

Vesical Hæmaturia.—Blood derived from the mucous membrane of the bladder is less immediately mixed with the urine and is generally passed in largest quantity towards the end of micturition. Not infrequently it is passed as blood-clots. The commonest causes of vesical hæmaturia are villous tumours and calculus. In both these conditions the hæmorrhage is due to the mechanical rupture of small vessels. Rupture of varicose veins is a less frequent cause. Slighter degrees of bleeding may be due to acute cystitis, passive congestion, tubercular ulceration, or the presence of the *Bilharzia hæmatobia*. In the latter case, ova with lateral or terminal spike will be readily found in the deposit obtained from the urine. See BLADDER, Diseases of; and ENTOMOZOA.

Urethral hæmaturia.—When the blood is derived from the urethra it is always expelled at the beginning and occasionally also at the end of the act of micturition, is often clotted, and is never intimately mixed with the urine. Its chief causes are inflammation and ulceration, direct injury, or the effects of the passage of a calculus. See URETHRA, Diseases of.

Accidental hæmaturia.—This may occur during menstruation or from the admixture of any uterine or vaginal discharge containing blood. The blood is rarely intimately mixed with the urine, and when it is, is generally of a brighter colour, which arouses suspicion as to its origin. If malingering is suspected the urine should be passed under observation or withdrawn by a catheter.

RECOGNITION.—Whenever the urine contains a

large amount of blood, the appearance is sufficiently characteristic, but when the amount is only sufficient to impart a smoky tint to the urine, microscopical and chemical examination is essential.

I. The *microscope* furnishes the most satisfactory test, as it is the only means by which the presence of blood-corpuscles can be ascertained. The urine should be allowed to stand for some hours, or the deposit be obtained by means of a centrifuge. The corpuscles will be globular or crenated according to the specific gravity of the urine; but their colour is often so pale that it fails to characterise them. They may be distinguished from pus-corpuscles, vegetable spores, and fragments of dumb-bell crystals by characters which can readily be seen in the Plates illustrating the article on Urinary Deposits.

The chemical examination comprises three tests, of which the first, which is most generally employed, is least reliable.

II. This is known as Almen's or the *Guaiacum-test*. Two or three drops of a freshly prepared simple tincture of guaiacum are added to about a drachm of urine, and the mixture shaken. Upon this is then poured about half the quantity of a 15-per-cent. solution of peroxide of hydrogen in ether (ozonic ether). If blood be present, the lower portion of the ozonic ether gradually becomes blue. This reaction is given by saliva, iodide of potassium, and other substances, and is not therefore wholly trustworthy.

III. The *Hæmin-test* is more reliable. The urine should be rendered alkaline by the addition of liquor potassæ and then boiled. A portion of the reddish-brown deposit which forms (*Heller's Test*) is placed on a glass slide and dried. A drop of *glacial* acetic acid and a small crystal of common salt are then added; the slide is next briskly warmed over a spirit lamp, and then set aside to cool. On microscopical examination hæmin-crystals may be found.

IV. A *pocket-spectroscope* furnishes a readier and no less reliable test. The reddish-brown precipitate described in the last test is placed in a test-tube, and shaken up in a little warm water. On placing the tube between the prism and the daylight, the characteristic absorption-bands will be seen. See SPECTROSCOPE IN MEDICINE.

DIAGNOSIS.—This rarely depends upon the character of the urine, although the microscopical examination of the deposit may reveal important evidence. The quantity of blood contained in the urine, the degree of admixture, and the microscopical examination of the deposit may be sufficient to suggest the cause, but a consideration of the symptoms and a careful examination of the patient are essential in forming a reliable diagnosis.

TREATMENT.—In the majority of cases the hæmaturia needs no treatment, and in those cases in which a large amount of blood is lost, absolute rest in bed and the administration of aperients are the only measures to be resorted to apart from the treatment of the diseases primarily responsible. For the treatment of these see the various articles on the Kidney, Bladder, and Urethra.

H. MONTAGUE MURRAY.

HÆMORRHAGIC (αἷμα, blood; and ῥήγνυμι, I burst forth).—Associated with hæmorrhage. The word is applied to certain inflammatory products or to effusions when they contain blood, as in *hæmorrhagic peritonitis*; and to varieties of certain diseases in

which extravasations or hæmorrhages from free surfaces occur, for example *hæmorrhagic small-pox*, *hæmorrhagic measles*, and *hæmorrhagic purpura*.

HÆMORRHAGIC DIATHESIS.—See HÆMO-PHILIA.

HÆMORRHOIDS (αἷμα, blood; and ῥέω, I flow).—SYNON.: Piles; Fr. *Hémorrhoides*; Ger. *Hämorrhoiden*.

DESCRIPTION.—The hæmorrhoidal vessels, and especially the veins distributed to the lower part of the rectum, are very liable to become dilated and varicose, giving rise to a disease termed *hæmorrhoids* or *piles*. When the plexus beneath the mucous membrane within the external sphincter is thus affected, the hæmorrhoids are said to be *internal*. When the veins beneath the integuments outside the muscle are enlarged, the hæmorrhoids are called *external*. Internal and external hæmorrhoids very frequently co-exist.

External Hæmorrhoids.—We may distinguish two kinds of external piles—(1) the *venous*; and (2) the *cutaneous*.

(1) The *venous tumour* consists of a softish elevation of the skin near the margin of the anus, of a rounded form, and a livid or slightly blue tinge. On cutting into it, we find it is formed by a dilated vein or veins, which after inflammation will be occupied by a dark-coloured coagulum.

(2) The *cutaneous excrescence* consists of a flattened prolongation of skin, due to hypertrophy of the cutaneous layers, and is commonly pedunculated. It is generally the result of the first form—a projecting skin-tag left after absorption of the coagulum having undergone some hypertrophy. Often there is only a single broad flat excrescence at the side of the anus, but sometimes there are two—one on each side; and occasionally there are several encircling the anus. They are apt to become inflamed and oedematous. Similar excrescences occur as the result of irritating discharges from the bowel, and are common in stricture and chronic ulceration of the rectum.

Internal Hæmorrhoids.—Internal piles may be divided into three classes—(1) the *venous*; (2) the *columnar*; (3) the *nevoid*.

(1) The *venous pile* resembles the external venous pile, except that it is covered by mucous membrane and is within the sphincter.

(2) The *columnar pile* consists essentially of hypertrophy of the folds of mucous membrane which surround the anal opening—the pillars of Glisson. They have a red, almost vermilion, colour, an elongated form, and contain within them one of the descending parallel branches of the superior hæmorrhoidal artery (Hamilton). This pile is very vascular, bleeds copiously, and is made up of hypertrophied submucous tissue with many dilated arteries and veins.

(3) The *nevoid pile* is bright red, spongy and villous, and has been well compared in aspect to a strawberry. In structure it resembles a capillary nævus. It may bleed almost continuously.

Internal piles seldom attract attention until they have become so developed as to protrude at the anus in defecation. They then exhibit a remarkable diversity of appearance, according to their number, size, and condition. The protrusion may consist of only one large pile, found usually toward the perinæum, especially in women. More commonly there

are three distinct prominent growths, differing in size, one at each side of the anus, and a third in front—the last, the perineal, being the largest. In old cases they may be more numerous—as many as four or five. The distinction between them is commonly well-marked, but not always, for the piles sometimes merge into each other, so that the protrusion forms nearly a circular prominence. The aspect of extruded piles depends much upon their condition, whether congested, inflamed, or constricted by the sphincter. In an inactive state, and in a relaxed condition of the sphincter, they form softish tumours of a granular appearance, presenting just at the orifice of the anus; but when protruded and congested, they constitute large tense tumid swellings, of a deep red colour and smooth surface, which readily bleed. When hæmorrhoids are of large size, the integuments at the margin of the anus become everted, and form a broad band girding the base of the tumours. The skin thus everted is liable to be mistaken for external piles, and to be excised in operations—an error very likely to be followed by serious contraction of the anus.

ÆTIOLOGY.—Hæmorrhoids are a disease of middle and advanced age. They rarely occur before puberty; but very few persons in after-life altogether escape them. All circumstances which determine blood to the rectum, or which impede its return from the pelvis, tend to produce this disease. There is in many persons a natural predisposition to the complaint, which may be hereditary. But a predisposition is most frequently acquired by sedentary habits, indulgences at table, and neglect of the bowels. Hæmorrhoids, though a common disease in both sexes, occur more frequently in males than in females. Few women bear children without becoming in some degree affected by them; but the urinary and genital disorders of the other sex, combined with freer habits of living, leading to congestion of the liver, are still more fertile sources of piles. It must be remembered that piles may be merely a symptom in certain cardiac, hepatic, or uterine diseases.

SYMPTOMS.—The symptoms produced both by external and internal piles vary greatly in different subjects and in different stages of the complaint.

External piles cause a feeling of heat and tingling at the anus. A costive motion is followed by a burning sensation, and the excrescence becomes swollen and tender on pressure, so as to render sitting uneasy. This congested state of the pile may pass off; or it may lead to inflammation accompanied with considerable enlargement of the hæmorrhoid, forming an oval tumour, red, tense, and extremely tender. In such case phlebitis has ensued, and the pile-cavity is occupied by a coagulum. The inflammation may subside or go on to suppuration. When the matter is discharged, the clot of blood escapes with it, the abscess closes, and the dilated vein is usually obliterated, the pile being reduced to a small flap of integument. External piles rarely give rise to bleeding.

Internal piles, when slight, may exist for years, causing little inconvenience besides slight bleeding after a costive motion; with occasionally a feeling of fulness, heat, and itching just within the anus. If only small, they protrude slightly with the mucous membrane in defecation, returning afterwards within the sphincter. When of large size, the piles always protrude at stool, and require to be replaced, the patient usually pushing them up with his fingers. In a lax state of the sphincters, and in a loose

hypertrophied condition of the mucous membrane from which they spring, hæmorrhoids come down, even when the patient stands or walks about, so as to prove exceedingly troublesome, and to interfere with his taking walking exercise. In consequence of the irritation from pressure and friction to which the protruding piles are liable, their mucous surface becomes tumid and abraded, and furnishes a free mucous discharge tinged with blood, which soils the linen. They are often so sore that the patient is obliged to keep the recumbent posture, the pressure in sitting causing more or less uneasiness.

Persons subject to piles frequently suffer no inconvenience from them until irritated by an unusually costive motion, or by a smart purgative; or when, under the excitement of alcohol, the growths become congested and inflamed, and cause spasm of the sphincter muscle. Then they have what is termed an 'attack of piles'—that is to say, they experience a sensation of heat, weight, and fulness just within the rectum, followed by considerable pain at stool, and sometimes irritation about the bladder. These symptoms, which are often attended with febrile disturbance, arise from inflammation and swelling of the piles, which afterwards subside, but seldom without leaving some enlargement of the growths. Anæmia may follow upon continued bleeding; and reflex pains in the back, groin, and genitals are often complained of.

Strangulation.—When internal piles of some size protrude at the anus and are not returned, they are liable to be constricted and strangulated by the external sphincter. The contracted muscle impedes the return of blood, and occasions inflammatory swelling of the piles, which may become strangulated and gangrenous. In this way hæmorrhoids of large size have been known to slough off, the patient being relieved of the annoying complaint by a sort of natural process. An occurrence of this kind is attended with a good deal of pain and suffering, but is free from danger. In general, the extremities only of one or two of the larger growths perish, and the patients, though experiencing relief, are by no means cured of the disease.

Hæmorrhage.—One of the most common symptoms of internal hæmorrhoids—indeed that from which the name of the complaint is derived—is hæmorrhage, which occurs when the bowels are evacuated. The bleeding varies greatly in amount. Sometimes the motions are merely tinged with a few drops of blood; in other instances the quantity lost is considerable, several ounces being voided at stool. The bleeding may be irregular, occurring only after costive motions, or in certain states of health; or it may take place daily, going on even within the bowel, and producing the usual symptoms of derangement from continued losses of blood. The character of the bleeding also varies with the structural character of the pile, being, however, usually venous. There are persons who are liable to discharges of blood from the hæmorrhoidal veins, either at regular periods, or when, from good living or want of exercise, some plethora is induced. In these cases from three to six ounces of blood, or even more, pass away at stool, following the evacuation; and the blood which is voided is of a dark colour and evidently venous. Such discharges must not be rashly interfered with. They relieve congestion of the liver and kidneys, help to ward off attacks of gout, and prevent fits of apoplexy; so that in certain of these plethoric persons they are

rightly regarded as safety-valves. The bleeding from internal piles is undoubtedly in some cases arterial. Sometimes the blood may be observed to escape from the pile in jets. This is not evidence that it is arterial, but may be due to a regurgitant stream of blood forced through a rent in a vein by the pressure of the abdominal muscles. That bleeding from piles is always good for the health is quite a mistaken notion; and it is important that the practitioner should distinguish the bleeding taking place as a consequence of local disease, from that which arises from plethora, congestion of internal organs, or such a disease as cirrhosis of the liver.

TREATMENT.—When piles are small and cause but little inconvenience, the treatment is very simple. Persons with this complaint should take stimulants in great moderation, if at all; and in most instances they would do well to abstain entirely from alcohol. Many individuals never suffer from piles except after taking a glass of spirit-and-water, or a few glasses of wine. Such persons should become water-drinkers. Active exercise in the open air should be taken daily; and the patient should avoid sitting too long at the desk, because it is by prolonged sedentary occupation and the neglect of the rules of health that hæmorrhoidal complaints are encouraged. Chairs with cane seats are to be recommended. The bowels must be carefully regulated, so as to avoid hard and costive motions, as well as too frequent action. Irritating the rectum by active and repeated purging is more hurtful even than constipation. In regulating the bowels, a simple enema of half a pint of cold water, injected after breakfast, answers most admirably, and is more efficacious than purgatives. If aperients be needed, preference may be given to confection of senna, cascara, or the compound liquorice powder. Carlsbad salts, or the foreign mineral waters—the Pullna, the Friedrichshall, or the Hunyadi János—taken in the morning fasting, answer well with many persons, and ensure a comfortable relief. The diet must be simple and moderate, and the habits of the patient regular. The relief afforded by this palliative treatment is often remarkable.

Ordinary bleeding may be met by injections of cold water, or by some astringent injection or ointment; among these may be named a solution of sulphate of iron (10 grs. to ℥j), or preparations of tannic acid or rhatany. When the bleeding is copious, injections are not so successful, and operative treatment often becomes necessary. As useful local applications may be mentioned, the ointment of galls and opium, a combination of morphine and tannic acid, an ointment containing menthol, and injections of hazeline, or the local application of hazeline after each motion.

External piles when large and troublesome, and internal piles when they protrude at stool, and are not easily reduced, or are subject to inflammation, ulceration, and frequent bleeding, can be removed only by operation. It is seldom desirable to operate upon piles developed during pregnancy, or upon hæmorrhoids occurring in the course of organic disease of the liver.

T. B. CURLING. FREDERICK TREVES.

HÆMOSIDERIN (αἷμα, blood; and σίδηρος, iron).—A generic name including all iron-containing pigments derived from hæmoglobin in the tissues. Hæmosiderin gives the ordinary reactions of iron,

and is found in any part where excessive destruction of blood-corpuscles has taken place. Like hæmatoidin, with which it is frequently mixed, it may exist in both granular and crystalline forms. See ANÆMIA, PERNICIOUS.

HÆMOSTATICS (αἷμα, blood; and στατός, stopped).

DEFINITION.—Internal remedies and local applications which arrest hæmorrhage.

ENUMERATION.—The chief hæmostatics are: Ligature; Pressure; Rest; Cold; Hot Water; the Actual Cautery; Astringents; the whole class of Styptic drugs; and Calcium Chloride and Nuclein, which have been shown to increase the coagulability of the blood. See HÆMOPHILIA.

ACTIONS and USES.—When taken in their widest sense, it is evident that hæmostatics must include all the various means which have been devised to stop bleeding. Externally we must vary our plan of treatment according to circumstances. No surgical principles are better founded than those which enjoin us to tie a wounded artery, and to apply pressure to a vein; and for the absolute arrest of hæmorrhage from any readily accessible part a most powerful aid has been provided in Esmarch's elastic bandage. When the bleeding depends on general capillary oozing, the application of ice may often prove effectual; and where this fails, recourse must be had to some of the numerous articles of the Pharmacopœia, already referred to, which possess styptic properties (see STYPTICS). An example of the successful application of a hæmostatic is the arrest of uterine hæmorrhage by means of injections of perchloride of iron, of hot water, or of ice-cold water. In the case of undue hæmorrhage from a leech-bite, if milder remedies, such as pressure, do not succeed, we may apply the solid nitrate of silver, or include the bleeding point in a loop of twisted suture.

Absolute rest is essential for the successful treatment of hæmorrhage; and the regulation of the diet and of the bowels is equally to be attended to. For the details of treatment in each particular form of hæmorrhage, the reader is referred to HÆMORRHAGE; HÆMOPHILIA; MELÆNA; and the diseases in which these conditions occur.

ROBERT FARQUHARSON.
SIDNEY PHILLIPS.

HÆMOTHORAX.—See PLEURA, Diseases of.

HAIR.—The diseases to which the hair is liable may be divided into two chief groups: those of nutrition and growth, including atrophic, hypertrophic, and pigmentary changes; and those associated with inflammation of the follicles, and the presence of parasites. The diseases comprised in the latter group will be found described under their respective heads, so that in this place we have to deal only with the first group.

DISEASES INVOLVING THE NUTRITION AND GROWTH OF THE HAIR.—Most of the alterations in the growth and colour of the hair are atrophic in their nature. The more common forms of atrophy produce various kinds of baldness; and in addition we have greyness or loss of the natural colour of the hair, and certain structural alterations, such as those met with in trichorrhæxis nodosa; these latter alterations, though not simple atrophies, yet belong to the atrophic group.

Alopecia or Baldness.—Baldness is of two kinds—*congenital* and *acquired*. *Congenital* alopecia is very rare; it is a malformation rather than a disease, and is generally associated with a defective development of the teeth. This condition is permanent.

Acquired baldness arises from many different causes. It may result (1) from *various forms of disease*; (2) from simple *defective nutrition and growth*; or (3) from *atrophic senile changes*.

(1) *Baldness from various forms of disease.*—Different diseases produce baldness in different ways, and they may be conveniently divided into four groups: acute febrile diseases; follicular inflammations; nervous affections of the skin; and parasitic diseases.

The baldness which follows *fevers* is always temporary, though often extreme. There is apparently an almost sudden death of the hair at the time of the fever, especially when there is long-continued high temperature, and this is followed by its falling off some two or three months afterwards. Parturition and some other illnesses besides fevers produce a similar result, though generally more slowly and persistently. The falling off of the hair which accompanies secondary syphilis often occurs without any visible eruption on the scalp.

Folliculitis, or inflammation of the hair-follicles, is one of the commonest causes of baldness. We meet with it in seborrhœa capitis, in sycosis, and in various pustular eruptions involving the hair-follicles. When produced in this way, alopecia may be temporary or permanent, according to the nature or the severity of the disease. All diseases of the skin which leave scars or obliterate the follicles lead to permanent alopecia of the parts affected. Erythematous lupus, scleroderma, and some forms of syphilis, are examples. It is especially the forms of alopecia resulting from folliculitis which are so much aggravated by the stimulating applications almost universally recommended by hairdressers, without regard to the cause of the malady.

The changes in the *nervous system* which produce baldness may be general, as in some cases of shock; or local, as in alopecia areata. Falling of the hair, which sometimes follows a blow or other injury to the nerves, belongs to this class. See ALOPECIA AREATA.

The *parasitic diseases* which lead to partial baldness are tinea tonsurans and favus, which are fully described under their proper headings.

(2) *Baldness from defective nutrition.*—Premature baldness from defective nutrition differs little from senile alopecia, and is often hereditary. The thinning of the hair in myxœdema is an example of this variety.

(3) *Senile Baldness.*—This differs from the preceding variety in degree only.

The treatment of this kind of alopecia, as might be expected, is not very satisfactory. Some good, however, may be done in the early stages by stimulating remedies. One of the best is a lotion consisting of vinegar of cantharides, ʒvj.; glycerin, ʒj.; spirit of rosemary, ʒij.; rectified spirit, ʒv. This should be dabbed on the scalp daily with a small sponge. Frequent and excessive sweating is certainly an exciting cause of premature baldness in those predisposed to the malady; hence its frequent occurrence in Europeans who live in tropical climates. See BALDNESS.

Pigmentary Changes.—Canities, or greyness, results from the deficient development of the natural pigment of the hair. It may be congenital or acquired. The extreme form of congenital canities is met with in albinos, in whom there is an absence of pigment in the skin and choroid as well as in the hair. In an irregular form it sometimes exists as a congenital white lock on the scalp or face, the surrounding hair being of a normal colour.

As an acquired alteration in the hair, canities is well known as a simple senile change. Premature greyness, not differing essentially from the senile change, is often met with in those suffering from any chronic disease, such as phthisis; it is also more or less hereditary. In all these cases the greyness is symmetrical. In an asymmetrical form it is met with in several diseases of the skin, especially in area, leucoderma, and chronic neuralgia of the scalp. The distribution of the grey hair and the history of the case will serve as a means of differential diagnosis.

In many cases of canities treatment is obviously useless. In those cases which admit of rational treatment, cantharides is by far the best local stimulant, as it has a tendency to excite the natural development of colouring matter, as may be often seen in the skin where a blister has been applied. Arsenic is usually the best form of tonic for the same reason.

Excessive growth.—Downy and almost invisible hairs may grow into strong and visible ones, but there is never any increase in their number; the great increase in their size sometimes leads to the erroneous belief that the actual number is greater than before. Sometimes the old hair is held in the follicle after the new hair has grown up, but this is not a true increase of numbers. An excessive growth of hair is not uncommon, and is a source of annoyance when it occurs on the face in women. *See* DEPILATORIES.

Structural changes.—*Trichoclasia*, or *trichorrhexis nodosa*, is the most important and best-known change in the structure of the hair. To the naked eye the hairs appear to be marked with two, three, or more small bulging spots, somewhat resembling nits. The hairs very easily break at these points, which, examined under the microscope, seem to consist of spindle-shaped swellings of the shaft of the hair. In a more advanced stage this swelling partially bursts near its most distended part, and finally the hair breaks with a ragged fracture, so that the divided hair has the appearance of two brushes, the bristles of which are interlocked. When the separation is complete, a stumpy hair is left with a frayed or brush-like free extremity. A variety of this disease is sometimes met with in which a smooth fracture takes place, not at the spindle-shaped swellings, but in the intermediate parts of the hair. *Trichorrhexis* is chiefly met with in the hairs of the face, especially those of the chin.

Lepothrix.—Although this curious affection is a concretion rather than a structural change of the hair, yet it has that appearance to the naked eye, and may be conveniently referred to under this head. The hairs affected with this disease are those of the axillæ and the scrotum. The concretions, seen under the microscope, have usually a rounded and nodulated form apparently surrounding the shaft of the hair, but not symmetrically. Sometimes the concretion extends continuously for some distance along the shaft of the hair, giving it a feather-like appear-

ance. The hairs themselves are abnormally brittle. These curious concretions are associated with the presence of a short bacillus which penetrates, and grows beneath, the cortical scales of the hair-shaft. The disease is very difficult to eradicate. Shaving and antiseptic applications are the two therapeutic agents generally employed.

ROBERT LIVEING.

HAIR-BALLS.—*See* CONCRETIONS.

HALL, in Austria.—Common salt waters, with iodine. *See* MINERAL WATERS.

HALLUCINATION (*hallucinator*, I blunder).—A false perception of an organ of sense, for which there is no external cause or origin (*see* ILLUSION); as when a man in total darkness thinks he sees an object. Hallucinations of all the senses occur, the most frequent being those of sight and hearing. They may be found in persons not insane, but indicate a disordered state of brain.

HAMMAM-MELOUAN, in Algiers.—Thermal muriated saline waters. *See* MINERAL WATERS.

HAMMAM-MESKOUTINE, in Algiers (the *Aque Tibilitine* of the Romans).—Highly thermal saline springs, weakly mineralised. *See* MINERAL WATERS.

HAMMAM-R'HIRA, in Algiers.—A winter resort for invalids. Highly thermal waters. *See* MINERAL WATERS.

HAMMERMAN'S PALSY.—*See* OCCUPATION-DISEASES.

HANGING, Death by.—Hanging is the effect of suspension of the body by the neck by means of a ligature or noose, the constricting force being the weight of the body, wholly or in part, or the weight multiplied by the distance through which the body falls. The mode of death varies according to these circumstances. With a long drop, the method now usually employed in judicial hanging, and particularly if the knot is under the chin, death is not infrequently due to fracture, or displacement, of the cervical vertebræ, and injury to the medulla oblongata. Death may also occur, without such anatomical lesion of the cervical vertebræ, from shock or syncope, or, as it is termed by Casper, neuro-paralysis.

When death does not occur in either of these ways, it is the result of asphyxia from occlusion of the air-passages, or rather of asphyxia in combination with coma, caused by compression of the cerebral blood-vessels. Though compression of the carotid arteries and jugular veins may be maintained for a considerable time without a fatal result, if the trachea is open below the point of constriction—whereas death speedily ensues if the air-passages are also occluded—yet death may result from the disturbance of the cerebral circulation alone; and the two causes operate conjointly in every case, in varying proportions.

PHENOMENA.—When death is not instantaneous, as in cases of injury to the medulla, or from neuro-paralysis, convulsive movements of the type seen in asphyxia may continue for some minutes after suspension, and the heart may continue to beat for a considerable period after all other vital movements have ceased.

Subjects who have been partially hanged have described various sensations, more or less pleasurable, similar to those of cerebral congestion and narcotic stupor.

POST-MORTEM APPEARANCES.—The appearances found after death by hanging are not uniform or constant; and there is no single sign invariably present diagnostic of this mode of death. Indicative of suspension, but not necessarily of death so caused, is the mark of the cord on the neck. Usually it is above the hyoid, passing obliquely upwards behind the ears, and losing itself in the occiput. But the position may vary according to the tightness of the noose before suspension, or the position of the head and direction of the pressure. It is generally single, but if the cord should have been twisted twice round the neck, two marks may be found, one circular and the other oblique. The characters of the mark differ somewhat according to the texture and thickness of the ligature. Usually it is a shallow groove or furrow, of a whitish or brownish hue and parchmenty consistence, occasionally abraded, rarely ecchymosed; but it may have livid edges or a chocolate tint. The appearances may vary in different parts of the same mark. The subcutaneous cellular tissue is compressed and silvery. Occasionally minute extravasations are seen in the deeper layers of the skin. The middle and internal coats of the carotids are sometimes lacerated; and where the momentum has been great, lacerations of the cervical muscles, hæmorrhage in their vicinity, fracture of the larynx, rupture of the thyro-hyoid ligaments and fracture of the hyoid bone, and fracture or dislocation of the cervical vertebræ, with injury to the medulla and effusion into the spinal canal, have been found. All the appearances usually found in the neck in cases of hanging may be produced by suspension of the dead body, especially if the legs are pulled forcibly downward.

The face is sometimes, but not commonly, distorted and expressive of suffering. Usually it is placid and pale, though if the body have hung for some time, it becomes very livid. The eyes are sometimes very prominent, and the pupils are usually dilated. Frothy mucus may be found at the mouth and nostrils. The tongue is pressed against the teeth and indented, or it may be clenched between the jaws. The base of the tongue is injected. The hands are often tightly clenched, the nails even being driven into the palms. Erection, or semi-erection, of the penis in men, with expulsion of semen or prostatic fluid, and vascular turgescence of the genitals in females, with sanguinolent effusion, are occasionally observed. Expulsion of the contents of the bladder and rectum is likewise common. The condition of the brain varies. Congestion of the meninges is sometimes pronounced, at other times not very marked. The mucous membrane of the larynx and trachea is congested, and mucous froth is present. The lungs are at times pale and distended; at other times collapsed. The condition of the heart and venous system characteristic of asphyxia is common. Marked redness of the mucous membrane of the stomach, simulating irritant poisoning, has been occasionally noted. The determination of the fact of death by hanging depends on a consideration of these various phenomena, and the absence of other causes of death.

ACCIDENT, SUICIDE, OR HOMICIDE?—Hanging is rarely homicidal. It signifies great disproportion of strength between the assailant and the victim;

and therefore, in the absence of this condition, there will be injuries indicative of a struggle. Apart from collateral circumstances, homicide can only be argued from the presence of such injuries as could not have been self-inflicted or caused accidentally during the act of suspension. Occasionally hanging is accidental, as in foolish experiments and insane imitation. It is not necessary that the body should be entirely off the ground to cause death by hanging. Many instances are recorded of suicide by hanging in most extraordinary positions calculated to throw the greater part of the body-weight on the noose.

TREATMENT.—This is rarely called for, except in accidents or attempted suicide. The body must be cut down, and artificial respiration employed. Venesection may be had recourse to for relieving cerebral congestion. *See* **ARTIFICIAL RESPIRATION**; and **RESUSCITATION**. **D. FERRIER.**

HAY-FEVER.—**SYNON.** : *Catarrhus astivus*; Bostock's Catarrh; Hay Asthma; Fr. *Asthme d'été*; Ger. *Frühsonnencatarrh*.

DEFINITION.—A catarrhal affection of the mucous membrane of the eyes, nose, mouth, pharynx, larynx, and bronchi, accompanied by dyspnoea; induced in persons predisposed to it by the action of the pollen of various plants, chiefly of the Graminae; prevalent during the hay-season, but subsiding at its close; and varying in severity according to certain atmospheric conditions, and the amount of pollen present in the air.

ÆTIOLOGY.—Hay-fever exists in Europe and North America, and it is especially common in England, where the number of cases is annually double that of any other country. The Anglo-Saxon race appears more liable to it than other races. It prevails more among men than women, probably because the former are most exposed to the atmosphere; and inhabitants of towns visiting the country are more liable to attack than the country-people themselves. J. N. Mackenzie of Baltimore assigns hay-fever to an exalted condition of the nasal erectile tissue, and especially the portion covering the posterior end of the inferior turbinated bone and the septum immediately opposite, rendering it more sensitive to the action of pollen and other irritants; and he maintains that destruction of this erectile tissue by the galvano-cautery cures the disease. Turbinctomy has been followed by complete relief (Lockard).

The disorder has been ascribed by some writers to the sun's heat in the summer months, also to certain odours, vegetable and animal; but the experiments of Blackley show it to be due to the

specific influence on certain mucous membranes of the pollen-grains of the following natural orders of plants: Ranunculaceæ, Papaveraceæ, Fumariaceæ, Crucifereæ, Violaceæ, Caryophyllaceæ, Geraniaceæ, Leguminosæ, Umbellifereæ, Rosaceæ, Liliaceæ, Compositæ, Graminaceæ, and others, both exotic and native. Different kinds of pollen were applied to the mucous membrane of (1) the nares, (2) larynx, trachea, bronchial tubes (by inhalation), (3) conjunctivæ, (4) tongue, lips, and fauces; and in all these cases it produced the symptoms of hay-fever, the pollen of grasses being most potent. Among these, *Secale cereale*, or rye, exercised most marked effects, though greater influence is generally attributed to *Anthoxanthum odoratum*.

It has been found that large quantities of pollen float in the air during the summer months; and that the number of cases of hay-fever depends on the amount present, which increases in warm, damp weather, decreases when it is very dry and hot, and often nearly disappears after heavy rain. Cold weather reduces the number of sufferers by checking the inflorescence of plants. The higher strata of the atmosphere appear to contain more than that immediately overlying the soil; and Blackley found the greatest number of pollen-particles at between 1,000 and 1,500 feet above the earth's surface, whither they are probably carried by aerial currents. The number of pollen-grains present reaches its maximum in June, when Blackley collected 880 in a day on a square centimetre of glass. The size and forms of the pollen-grains vary greatly in the different species, but this does not seem to influence their action, which appears to depend on the pollen-sac absorbing moisture from the contiguous mucous membrane and bursting, when the minute granules it contains are thus extruded, and cause irritation.

SYMPTOMS.—An attack of hay-fever generally occurs without any premonitory disturbance, immediately on the application of the pollen to the mucous surfaces—for instance, when the person enters a hay-field. The first symptoms are itching of the parts with which the particles come in contact, beginning with the hard palate and fauces, and then extending to the nostrils, eyes, and face, though, if the wind be strong, the eyes may be first attacked. The catarrhal stage follows, marked by violent fits of sneezing, and running from the eyes and nose, with occasional pains in the head and in the frontal sinuses; then the submucous tissue of the nares swells; and in a short time both nostrils become blocked and impervious to air. A change to the recumbent position, however, if the patient lies on one side, will often re-open the uppermost nostril, while the other, as the result of gravity, becomes still more occluded. The sneezing will continue without fresh application of pollen, as at night, when the subsidence of the swelling restores, or even exaggerates, the sensibility of the Schneiderian membrane. The *ala nasi* become red and inflamed, and occasionally bleed. The discharge after this becomes less in quantity, inspissated and puriform, and finally subsides. In the eyes, the swelling of the submucous tissue causes closure of the, lacrymal canals and nasal ducts; and considerable injection of the conjunctival capillaries is apparent. Sometimes, but rarely, oedema of the eyelids follows. Similar to the nose-symptoms are those occurring in the throat, some swelling taking place in the pharynx, which gives rise to partial closure of the Eustachian tubes, and hence to a certain degree of

deafness. Slight feverishness is occasionally present, the pulse quickening to 100, and the temperature slightly rising; but in a large number of cases pyrexia is entirely absent. The changes which take place in the mucous membrane of the air-passages give rise to asthmatic symptoms, such as tightness of the chest, difficult and wheezy breathing, with prolonged expiration, and some dry cough, followed, at the close of the attack, by expectoration.

The catarrhal symptoms are, however, more characteristic than the asthmatic, which are not invariably present.

The liability to attack lasts generally from three to four weeks in summer, but its duration depends on the presence of the exciting cause, which, if not removed, may cause the malady to last for months. A fall of rain will diminish the disorder by clearing the air of pollen; exercise, which increases the number of respirations and, therefore, of pollen-grains inspired, will render it more severe; while each attack makes the individual more susceptible to this subtle influence, and consequently augments the probability of other seizures. As a rule, hay-fever has no complications, and passes away completely on the removal of the exciting cause. Constant recurrence of the attacks has been noticed to lead to deafness, owing to catarrh of the Eustachian tubes.

DIAGNOSIS.—The diagnosis of hay-fever from other affections is easy, as the fact of the catarrhal symptoms occurring only in summer separates it from an ordinary 'cold in the head;' while their combination with dyspnœa in hay-fever prevents it being mistaken for spasmodic asthma arising from other causes, in which there is usually no catarrh.

PROGNOSIS.—The prognosis is favourable if the patient be removed from the exciting cause, as the asthmatic symptoms seldom, if ever, lead to pulmonary emphysema, or to any permanent change in the bronchi.

TREATMENT.—The most obvious course in the treatment of hay-fever, but not always the most easy one, is to avoid exposure to pollen. Blackley notices that a small amount of this material might exist without giving rise to hay-fever, but if ten particles of pollen were detected on the glass slide exposed to the air for twenty-four hours, symptoms were sure to appear in persons liable to it. Sufferers from this complaint should avoid hay-fields, hay-ricks, and much exposure and exertion in the country during the hay-season, and should remain to a great extent within doors; but, where circumstances admit, change to the seaside is highly desirable, and it frequently effects a speedy cure. Even on the coast some care must be taken to select a locality free from vegetation; for if the wind blows from the land, and hay-grass be flowering at the time, an attack may be induced. Choice should be made of a seaside place backed by high cliffs, and where the prevailing winds are from the sea. Another method of avoiding attacks is by sea-voyages or short yachting cruises, undertaken during the hay-season, and many sufferers enjoy complete exemption in this way. Of other localities, high mountain stations, where there is more grazing than hay-growing, and closely inhabited cities with few parks or grassy squares, are to be preferred. Carbolised cotton-wool and other available respirators are sometimes used with advantage.

The medicinal treatment consists, first, in combating the general predisposition to the complaint

by tonic measures; and, secondly, in allaying the local irritation.

The first object is best achieved by shower-baths, and by such tonics as iron, quinine, nux vomica, sulphate of zinc, and arsenic. Lotions of subacetate of lead or sulphate of zinc applied to the eyes and inner surface of the nostrils give some relief; but the writer has found the most successful results from brushing the interior of the nostrils and pharynx with a solution of hydrochlorate of cocaine (20 per cent.) with a curved brush. Various sprays are exceedingly useful, such as those of solutions of carbolic acid (eight grains to an ounce), sulphurous acid (equal parts with water), sulphate of quinine (two grains, with acid, to an ounce), and tannic acid (four grains to an ounce); but the best of all is a solution of cocaine (8 to 10 per cent.) which reduces the sensibility of the parts affected. The spray may be applied, with proper precautions, to all the irritated surfaces—eyes, nose, throat, and larynx—with great relief.

C. THEODORE WILLIAMS.

HEADACHE.—SYNON.: Cephalgia; Fr. *Douleur de tête*; Ger. *Kopfschmerz*.—Pain or uneasiness in the head is very variable in its nature, and is produced by a great number of causes. It is present at some period or other in the course of most acute, and many chronic diseases; and may be associated or not with organic change in the brain, or in other organs of the body. See PAIN IN VISCERAL DISEASE.

SYMPTOMS.—Headache presents many varieties. It may be slight or most intense; superficial or deep-seated. It may be more or less confined to particular parts, as the forehead, the temples, the occiput, or vertex. Sometimes the pain is limited to one spot, producing the sensation as if a nail were being driven into the head, when it is called *clavus*. It may extend over one side of the head, as in hemicrania, or *megrin*; or be generally diffused. Headache presents every variety of character—dull, sharp, cutting, &c. Its accession may be sudden or gradual; and the paroxysms may be of the shortest possible duration, or may extend over hours, days, or months. The pain may be simple, or associated with various perverted sensations, such as giddiness, tingling in the limbs, disordered hearing, or disturbances of vision.

VARIETIES.—For practical purposes headaches may be arranged in the following order:—

1. *Structural headache*, or headache dependent upon disease within the cranium.

2. *Congestive headache*.

3. *Nervous or sick headache*—hemicrania or *megrin*.

4. *Toxæmic headache*.

1. *Structural headache*.—This may be due to any of the many forms of disease of the brain, or of its membranes, such as meningitis, cerebral softening, abscess of the brain, and cerebral tumour; or it may be premonitory of cerebral softening. It is nevertheless often wanting in these disorders, and the locality of the pain, when present, by no means corresponds with that of the lesion. As a rule, the pain of organic disease is fixed and habitual, though sometimes, as in abscess or cancerous tumour, it may be of an intermittent character. If there be sickness associated with it, the sickness occurs without any apparent gastric disorder, and the pain continues after the sickness ceases. Stooeping, and

even the recumbent posture, aggravate the pain, while it is lessened by elevating the head. If organic disease be suspected, the collateral symptoms must be carefully scrutinised and weighed. It rarely happens that organic disease needs to be inferred from pain alone.

2. *Congestive headache*.—Many forms of headache depend upon a greater or less degree of congestion of the vessels of the brain; the congestion being either active or passive.

Active congestion may be caused by hypertrophy of the left ventricle of the heart, general plethora, catamenial irregularities, mental or emotional excitement, and other conditions. The pain in such cases is of an obtuse character, affecting the whole or a part of the head, particularly the forehead and occiput. It is accompanied by a sense of pulsation in the ears, flushed face, glittering eyes, and giddiness on stooping.

Passive congestion may be produced by dyspnoea, by asthma, by valvular disease of the heart, or by disordered action of the liver, bowels, and skin; it may be an after-effect of drunkenness; or may result from any cause which can produce a state of debility in the vessels of the brain, such as general anæmia, exhaustion from fatigue, loss of blood, leucorrhœa, or that following over-excitement, mental exertion, or bodily fatigue—causes which all favour congestion. When the headache is induced by anæmia, debility, or indigestion, the pain occurs generally across the forehead or at the top of the head.

3. *Nervous or sick headache, hemicrania or megrim*.—This disorder is discussed in a separate article. See *MEGRIM*.

4. *Toxæmic headache*.—The headache which attends all fevers and inflammatory disorders, though due in some measure to cerebral congestion, is chiefly caused by the action of the blood, altered in character and elevated in temperature, on the nervous elements of the brain. In uræmia likewise the headache, which frequently precedes or accompanies the other symptoms pointing to the existence of renal disease, results from the morbid condition of the blood. So also, in some persons, breathing the impure air of a crowded room, or the products of the combustion of coal-gas, will, by the imperfect decarbonisation of the blood, speedily produce a headache.

DIAGNOSIS.—Besides the above varieties of headache, pain about the head external to the brain may be produced by *rheumatic* affections of the scalp, with tenderness of the skin and rheumatism in other parts; by *syphilitic* affections of the periosteum or bone; by *inflammation* of the scalp, commencing erysipelas, &c.; and by trigeminal and other varieties of *neuralgia*. Headache may be discriminated from neuralgia by its mode of accession; by the generally longer duration of the attack; and by the more complete intermissions.

TREATMENT.—The treatment of headache must necessarily depend upon the peculiarities of each individual case. In organic or toxæmic headache, the disease with which it is associated, and not the symptom itself, will of course be the object of consideration, and the treatment will be found discussed in connection with these special morbid states. The same remark applies to many forms of congestive headache, such as those produced by disease of the heart, asthma, &c. If catamenial irregularities or

uterine disorders are the exciting cause, these must be treated by appropriate measures. If anemia or debility be present, then, in the intervals between the paroxysms, iron in some form, either alone or in combination with quinine or some vegetable bitter, must be given. During the paroxysms a little sal volatile, a cup of soup or strong tea or coffee, or some weak alcoholic stimulant, may be of service. Where anemia is not a prominent symptom, or when the disorder assumes a periodical or intermittent character, quinine alone, in doses of two or three grains twice or three times a day, may be given; and if this fails to afford relief, arsenic is often of signal service. Great benefit is frequently afforded in the latter cases by the careful administration of alcohol or other alcoholic stimulant during the paroxysm. Except when the headache is associated with general plethora or active congestion, strong purgatives are to be avoided, and the bowels are to be regulated by the mildest aperient which will answer the purpose. The patient's habits and mode of life must also be strictly regulated; and care must be enjoined as to diet, sleep, clothing, and exercise, especially if the headache be associated with dyspepsia. If dyspeptic symptoms are prominent, or if the pain be connected with a gouty diathesis, then these disorders must be treated with their appropriate remedies.

If during the paroxysms the head be hot and the face flushed, warm or cold lotions, iced water, or eau-de-Cologne may be applied; a warm douching may be useful in some cases. Occasionally in severe attacks a few leeches may be placed on the temples or behind the ears with advantage, or a blister to the nape of the neck, but never if the face be pale and the pulse feeble. Compression of the temporal arteries with a pad, sustained pressure around the head, or holding the arms high above the head, will sometimes relieve severe congestive headache.

The treatment of sick headache is discussed under the article MEGRIM. P. W. LATHAM.

HEAD-NODDING OF INFANTS.—**DESCRIPTION.**—Head-nodding, or Spasmus Nutans, is a functional disorder of infancy, characterised by rhythmical movements of the head, which are usually associated with nystagmus.

ÆTIOLOGY.—It begins almost always during the latter half of the first year; two cases have been recorded in which it began as early as the sixth week, and it has begun as late as the twentieth month. Girls are affected rather more often than boys. A very striking seasonal relation is noticeable: of seventy-six published cases seventy began in the six months from October to March, and of these no less than forty-seven began in December or January. It occurs much more frequently in town than in the country, and in the poor than in the rich.

The causation of this disorder is obscure. Rickets is present in many cases, but often only in very slight degree, and it may be entirely absent. Debilitating diseases, such as measles, whooping-cough, or gastro-enteritis, have preceded the onset in some cases, and have been followed by relapses in others. In at least 9 per cent. of the cases head-nodding has followed shortly after a blow on the head from a fall. Dentition has certainly aggravated the movements in some cases, and in others they have subsided after the eruption of a troublesome tooth; but the condition may be present

before the period of dentition. Many of the infants thus affected live in dark rooms, and it has been suggested that, as in miner's nystagmus, which is also occasionally associated with nodding movements of the head, deficiency of light may be an important factor.

SYMPTOMS.—The first symptom is usually the curious movement of the head, which may be rotary as in negation, nodding as in assent, or lateral. The rotary movement is the most common, but is often combined with some nodding or lateral movement; nodding alone is rare. The movement is rhythmical and monotonous, varying in rate from about 30 to 120 per minute. As long as the infant is in the erect position it may be continuous, or may occur only at short intervals; it ceases in the recumbent position, and when the infant's attention is attracted; covering the eyes also stops it. The movement is perfectly easy, not jerky, and seems to cause the infant no discomfort.

Generally within a few days after the onset of the head-movement, sometimes before it, nystagmus in one or both eyes appears; this may be vertical, horizontal, or rotary, and may even have a different direction in the two eyes. If not limited to one eye, it is usually more marked in one than in the other. When horizontal in both eyes it is often convergent not conjugate. It is always a very fine, rapid nystagmus (3-4 per second); it may be continuous or may occur only when the child looks in certain directions. It is increased, or indeed may only be elicited, by fixing the head or by attracting the child's gaze to some object. Hippus and convergent strabismus have occasionally been observed. In looking at objects these infants often put the head on one side, or throw it back, or look out of the corners of their eyes in an odd fashion.

In several cases transient attacks of unconsciousness, like *petit mal*, have been noticed.

PROGNOSIS.—After a few weeks or months the head-movements gradually disappear, and shortly afterwards the nystagmus also ceases. The symptoms rarely persist beyond the age of eighteen months. There seems to be no tendency to epilepsy afterwards, nor is the intellect impaired.

DIAGNOSIS.—Mentally deficient children sometimes show irregular movements of the head which may be distinguished by their occurrence at a later age, and sometimes by their less rhythmical character. A to-and-fro swaying of the trunk is occasionally seen in the second and later years; in some cases it is a harmless habit, in others it is a form of masturbation, while in others again it appears to be epileptic (eclampsia nutans). The age, the involvement of the whole trunk, and in some cases its more purposive character, or the association of epileptic manifestations, may serve to distinguish it. Congenital head-nodding and nystagmus, which may be hereditary and persist through life, can only be distinguished by the history and subsequent course.

PATHOLOGY.—It seems certain that the condition is functional, but nothing further is known of its pathology. There are points which suggest that it is cortical in origin, and it may well be that the imperfect education of the cortical centres at this age favours such a disturbance.

TREATMENT.—Bromides seem to have some slight effect in diminishing the movements; phenazone has also seemed useful; but it is doubtful whether recovery is hastened by the use of drugs.

The infant should live in a well-lighted room, and any predisposing cause, such as rickets, must be treated with appropriate remedies.

HEALTH-RESORTS.—See CLIMATE; CLIMATE, Treatment of Disease by; and BATHS.

HEARING, Disorders of.—These disorders may be grouped under three classes, namely: (a) *Partial or complete loss of hearing, or deafness*; (b) *Exalted hearing* (so called); (c) *Perverted hearing or tinnitus*. They may be due to various conditions quite independent of any actual disease of the auditory apparatus, and only such causes of disordered hearing will be considered in the present article as are not due to changes in the conducting portion of the ear, which can be demonstrated by the different methods of examination, or to recognised affections of the nervous apparatus connected with hearing. These will be found discussed under the article EAR, Diseases of.

(a) *Partial or complete loss of hearing.*—Perhaps the deafness due to accumulations of cerumen, which so frequently interfere for a time with the hearing of persons whose ears are free from disease, should be regarded as disordered hearing, rather than as a symptom of a pathological condition. As nothing more energetic than careful syringing is required to remove such obstructions, it will be sufficient to observe that in this proceeding the nozzle of the syringe should be directed along the roof of the external canal. Among a very large number of people with the organs of hearing in an apparently healthy state, some few will be found upon whom, throughout their lives, certain notes produce no response. They will not, for example, be able to hear the sounds made by grasshoppers, or the singing of some birds—the call of a partridge, for instance, and in most persons, as age advances, the very high notes are lost. To prove this, it is only necessary to blow one of Galton's whistles in a room full of people, when a considerable proportion of the assembly will fail to catch the high notes, which are distinctly heard by the rest; and although this failure is also noticeable in many nervous affections, all other sounds will perhaps be heard quite normally by these individuals. Emotional influences play a very large part in the destruction or suspension of hearing, and this is especially observable in the case of women. The unexpected sight of a dead husband, hearing of the death of a dear friend, the proposal of a severe surgical operation on a relative, a quarrel, an alarm of thieves, and witnessing a carriage-accident, have each within the knowledge of the writer been followed by intense and sudden deafness, which has only been partially recovered from. The same effect has been noticed in men who have been subjected to prolonged mental strain, in connection with literary work, or during commercial crises. Complete loss of hearing, extending over several months, was on one occasion followed by perfect hearing in a girl of fifteen, on the first appearance of menstruation. The temporary effect of quinine and salicylic acid on the hearing is well

known, but when quinine has been administered in large doses, and for a long period, this special sense is not unusually injured permanently. Among the diseases which often induce a lasting deafness, without any perceptible local change in the conducting portion of the ear, may be included mumps, diphtheria, and many other infective diseases; for although in many instances the middle ear often suffers, this is not always the case, and the immediate cause of the deafness must be sought in the products of inflammation which have been left within the cranium. The same explanation is probably also the correct one in those instances where children lose for ever all hearing power after cerebral excitement or congestion. Habitual and obstinate constipation is sometimes attended with loss of hearing, which returns after the action of purgative medicine. A clot of blood within the cranium, while causing hemiplegia of the opposite side, may destroy the hearing on the same side as the effusion; and a case is on record in which closure of the cerebro-spinal foramen gave rise to this symptom.

(b) *Exalted hearing.*—What is termed 'exalted hearing' will generally, on careful examination, be found to be not so much a definite change in the capacity of the hearing apparatus to receive impressions, as an inability on the part of the patient to receive such impressions without an undue effect on the nervous centres being produced. Thus in many inflammatory states of the brain or its membranes this symptom is often a prominent one. It is also not uncommonly met with in hysterical and nervous persons.

(c) *Perverted hearing.*—Attendant on most of the above examples, and closely allied to deafness, is the often persistent tinnitus; but there are conditions in which this distressing symptom is the chief and solitary trouble. Thus tinnitus, with a feeling of pulsation in the ear, is occasionally the first warning of an intracranial aneurysm; while a furious tinnitus and the hearing of strange noises sometimes precede an attack of acute mania. Patients who have been the subjects of malarial fevers and sunstroke often complain of tinnitus; and as in all cases of disease of the ears, when present, it is the most intractable of symptoms, so it is when the ears have not been the seat of any malady or injury.

TREATMENT.—Since all the above states of disordered hearing may strictly be said to be due to causes which are in themselves abnormalities of one part or another of the organism, it is to these that the treatment will naturally be directed rather than to alterations in hearing which in truth are merely symptoms. See EAR, Diseases of; and TINNITUS.

HEART, Abscess of.—See **HEART, Inflammation of Walls of.**

HEART, Aneurysm of.—**DEFINITION.**—A simple depression or a sacculus formed in the walls of the heart and communicating by an orifice, varying in size, with one or more of its cavities.

ÆTIOLOGY AND PATHOLOGY.—Sacs connected with the cavities of the heart have occasionally been found at birth. They must be regarded as congenital malformations. The essential condition which leads to acquired aneurysm of the heart is a change in a portion of the myocardium, by which the resisting-power of the affected part against the pressure of the blood within the cavity is diminished. Under such circumstances a simple depression, corresponding to the weakened spot, may be first formed on the inner surface of the heart. This gradually extends through the cardiac wall towards the external surface, where the resistance becomes less, and where a pouch or sac is then formed, communicating with the cavity of the heart, by a wide or narrow neck. Weakening of the heart's wall may be due either to inflammatory processes, including syphilis and tuberculosis, or to necrosis of the muscular elements, following upon obstruction of the blood-supply.

(a) *Inflammation* affecting the endocardium may extend to the substance of the heart and lead to softening or ulceration : both conditions have been found in connection with aneurysm. In pyæmic states abscesses may form in the walls of the heart, and softening of tubercular masses may also occur there ; cases are recorded in which, the contents of the sac thus formed having been discharged into the circulation, the cavity became converted into an aneurysmal pouch. Syphilitic deposits in the myocardium may result in the formation of patches of fibrous tissue which are liable to yield before the pressure of blood and form aneurysms.

(b) *Degenerative changes* in the muscle-fibres, due to blocking of small branches of the coronary arteries, are also the cause of fibrosis affecting portions of the myocardium. The muscle-fibres undergo fatty changes and are absorbed, their place being taken by a new growth of scar-tissue. Stretching of this fibrous tissue may give rise to aneurysm.

Cardiac aneurysm occurs with much greater frequency among males than among females (45 : 17.

Quain). It may occur at any period of life, acute inflammation being more often the cause in younger persons, degenerative changes in older subjects.

MORBID ANATOMY.—On laying open the pericardium in cases in which aneurysm of the heart exists, adhesions which are more or less universal, or which may be limited to the seat of the disease, are very frequently found. The heart itself is generally enlarged ; and where the aneurysm projects externally it is altered in shape—so much so in some instances that the organ looks like a double heart. The sac may project from the walls as a rounded or conical tumour ; or may assume the appearance of an elongated sac winding round the base of the aorta. Again, nothing abnormal may be observed until the heart is laid open, when a depression or an opening may be discovered in the walls of the ventricle, or in the septum. In rare instances more than a single pouch is formed : there may be several, each communicating with the cavity of the heart by a separate opening, or all by a common neck. The size of the tumour may vary from that of a bean to that of an average-sized cocoa-nut. The opening leading into the pouch may be the widest part of the sac, the aneurysm being a mere depression like a watch-glass or half an egg, or there may exist a constricted or defined neck, leading to a tumour bulging from the walls. The size of the opening may vary from a couple of inches across, to one capable of admitting only a probe. The neck is, in a few cases, described as hard and cartilaginous ; in others, as being smooth and regular, or jagged and irregular. The wall of the aneurysm may consist of practically unaltered heart-substance or of fibrous tissue without any trace of muscular elements. All transition-stages between these extremes may be met with. The thickness of the wall varies from that of a sheet of paper to a quarter of an inch or even more. The two layers of pericardium are frequently adherent over the aneurysm, thus tending to strengthen the sac. The aneurysmal cavity in the majority of cases is lined by smooth membrane ; but in a few instances, apparently of acute formation, the walls may consist of muscular fibres, torn and separated by the blood which has been extravasated among them. The contents of the sac are generally in the form of blood-clots or laminated fibrin, the outermost layers of which may be more or less organised and adherent to the wall.

SEAT.—In the great majority of cases the left ventricle is the part affected (52 out of 56 cases. Quain). Aneurysms of the ventricular septum affecting the 'undefended space' stand on a somewhat different footing from others, as they are probably due partly to developmental defect and partly to endocarditis.

SYMPTOMS.—Usually cardiac aneurysms are only discovered after death, having given rise to no definite symptoms during life. In a few cases symptoms, such as pain, dyspnoea, cyanosis, palpitation, and irregularity of the pulse, may be present, and may be accompanied by a murmur. It is thus evident that the symptoms of aneurysm are such as may exist in other lesions of the heart ; and it is extremely doubtful whether we have at our command the means of diagnosing the existence of this condition.

TERMINATIONS.—Death may result from the disturbance of the heart's action, induced by the presence and the extent of the disease ; from the aneurysm opening into the pericardium ; or from its

burrowing in the wall of the heart, and opening into a cavity of the organ other than that from which it originated. Lastly, one or two cases are recorded in which the progress of the disease had apparently been arrested by the walls of the sac becoming indurated or calcified.

DIAGNOSIS, PROGNOSIS, and TREATMENT.—Since it is probably impossible with our present means of diagnosis to ascertain the existence of a cardiac aneurysm, the question of prognosis does not arise practically, nor is treatment possible. It is well, however, to bear in mind that in cases of heart-disease in which the influence of syphilis cannot be excluded it may often be advisable to try the effect of full doses of iodide of potassium. The benefit of this salt is proved in other forms of aneurysm, and it might also prove serviceable in the cardiac variety. Apart from this, treatment could only be directed in individual cases to reducing arterial resistance, combating any signs of cardiac failure which may be present, and mitigating pain and distress.

HEART, Apoplexy of.—See HEART, Hæmorrhage into the Walls of.

HEART, Atrophy of.

DEFINITION.—Diminution in the size and weight of the heart, without any qualitative change in its structure.

ÆTIOLOGY.—Atrophy of the heart occurs as part of general wasting, provided that the wasting is not the result of any disease which throws additional work upon that organ. The most marked cases of cardiac atrophy are met with in slowly growing carcinomata. In one case of cancer of the pylorus, the heart weighed only $3\frac{1}{8}$ ozs. In chronic pulmonary tuberculosis the diminution in the weight of the heart is less marked, and in nearly half the cases the heart is the normal, or more than the normal, size. This result may be due to the obstruction to the circulation through the lungs. The heart also atrophies when the demands upon it are diminished. Thus amputation at the hip-joint in a young subject is followed by appreciable diminution in the size of the organ.

MORBID ANATOMY.—The heart is uniformly diminished in size as regards both its walls and its cavities. The muscular tissue generally wastes more than the fibrous tissue, and the pericardium may therefore present an opaque and slightly puckered appearance. For the same reason the consistence of the walls is often slightly increased and the section darker than normal. The muscular fibres are small and contain an excess of pigment. Fatty degeneration frequently accompanies atrophy. The co-existence of this change will modify the appearances. See HEART, Fatty Degeneration of.

SYMPTOMS.—Since the size of the heart is proportionate to the demands made upon it there will be no symptoms of cardiac failure unless fatty degeneration be also present. The physical signs are a slightly diminished præcordial dulness, a feeble but not diffused impulse, an apex-beat slightly within and above the usual situation, and possibly a diminished area over which the sounds are audible.

DIAGNOSIS.—From a consideration of the etiology of the condition it will be seen that this is a matter of no importance. It depends upon the existence of a lessened necessity for work, and upon the re-

cognition of the physical signs just given. Emphysema and other causes of diminished cardiac dulness and weakened cardiac impulse must be excluded.

TREATMENT.—The treatment of atrophy of the heart is the treatment of the disease upon which it depends.

HEART, Dilatation of.—**DEFINITION.**—In dilatation of the heart there is uniform enlargement of one or more of the heart's cavities. Dilatation is usually associated with hypertrophy.

ÆTIOLOGY.—The occurrence of dilatation implies that the walls of the heart which yield are too weak to resist successfully the internal pressure to which they are exposed. This defective relation may be due either to actual enfeeblement of the walls of the heart; or to excessive blood-pressure, which even the healthily constituted walls are unable to withstand. The enfeeblement of the walls may be a consequence of acute or chronic degeneration, or may be inherent but unconnected with visible textural disease. The excessive blood-pressure may be dependent on actual obstruction to the circulation; on overfilling; or on undue rapidity of action, which (other things being equal) implies an unwonted expenditure of force. As a matter of fact, however, dilatation and hypertrophy are generally if not always associated; and the processes by which these combined conditions are attained are more complicated than the foregoing statement might lead one to suppose. It will be convenient, therefore, to consider certain cases *seriatim*.

1. In obstructive disease at the aortic orifice; in general stricture of the minute systemic arteries, such as occurs in connection with contracted granular kidneys; and indeed in all cases in which resistance is offered to the free discharge of blood from the left ventricle, progressive hypertrophy of the walls of that ventricle takes place. But the hypertrophy may be complicated even from the beginning with dilatation. The hypertrophy, at any rate at first, is compensatory, and may be taken as a measure of the excess of resistance which the heart is called upon to overcome. The dilatation, however, is not strictly compensatory, and is probably to be regarded as a measure of the inability of the walls to cope fully with the extra work required of them. It is, moreover, obvious that the occurrence of dilatation, by increasing the area of resistance to the intra-ventricular blood-pressure, increases *pro tanto* the muscular effort requisite for the propulsion of the blood into the aorta; and by enlarging the capacity of the ventricular cavity and consequently the amount of blood to be discharged from it, on that account also throws additional labour on the muscular walls of the ventricle. Thus hypertrophy and dilatation react on one another; and hypertrophy, which probably at first compensates for the mechanical obstacle to the discharge of the normal contents of the ventricle, tends, later on, to compensate not only for this but for the virtual disability of the heart which associated dilatation entails.

2. In regurgitant disease at the aortic orifice, hypertrophy and dilatation of the left ventricle also

take place. But in this case, while the hypertrophy probably reaches a higher degree of development than in simple obstruction, dilatation preponderates from first to last; and the ventricle attains larger dimensions than in perhaps any other form of disease. In this case there is no impediment to the escape of blood through the aortic orifice, and therefore *primâ facie* no need for compensatory hypertrophy. There is no doubt that here hypertrophy follows dilatation. The immediate effects of regurgitation are, that during diastole the ventricle becomes more rapidly and completely filled with blood than it does under other circumstances; that hence the subsequent contraction of the auricle tends to distend it unnaturally with blood—*dilatation from overfilling*; and that during the whole of this period the walls have also to sustain the backward pressure of the systemic arterial blood. The result is that, on the principles above enunciated, the walls of the ventricle have to encounter a larger area of pressure, and to expel a larger amount of blood, than natural, and hence are called upon to make excessive effort, and hypertrophy ensues. Thus dilatation from overfilling causes hypertrophy; and both, acting continuously, promote the progressive increase in the capacity of the ventricular cavity and in the thickness of the ventricular walls.

In both cases, but more especially in the latter of them, the ventricle ere long fails to discharge its contents sufficiently into the aorta at each contraction, and the retention of this residual blood becomes an important factor in promoting dilatation—*dilatation with failure*; *residual dilatation*.

3. The effects of continued violent action of the heart, whether caused by nervous influence or by muscular effort, are much the same as those of obstructive disease. For both increased rapidity of contraction and increased amount of blood pouring into the heart, to be expelled at each beat (other things being equal), imply increased expenditure of force; and the persistence of either or both of these conditions causes, therefore, the supervention of hypertrophy and dilatation.

4. The above discussion relates especially to dilatation and hypertrophy of the left ventricle. But, *mutatis mutandis*, it applies with equal force to dilatation and hypertrophy of the other sections of the heart. Thus, in mitral valve-disease, the left auricle undergoes hypertrophy and dilatation—dilatation from overfilling preponderating in regurgitant disease of the valve, hypertrophy preponderating in obstructive disease.

5. In pulmonary valve-disease the right ventricle becomes hypertrophied and dilated—the dilatation being greatest where there is pulmonary regurgitation, the hypertrophy being greatest where the disease is obstructive.

6. In tricuspid valve-disease the right auricle suffers, becoming chiefly dilated in the presence of tricuspid regurgitation, chiefly hypertrophied when there is obstruction. And thus, also, just as when the systemic circulation is impeded the left side of the heart suffers, so when the pulmonary circulation is obstructed, the right side of the heart undergoes enlargement.

In all these cases, therefore, hypertrophy and dilatation seem to result concurrently; but whether the one or the other condition preponderates, depends partly on the particular nature of the cause to which the hypertrophy and dilatation are due,

partly on the inherent strength or weakness of the cardiac walls. In all cases, too, the other cavities of the heart, besides that primarily and directly implicated, suffer, according to their position, from the effects of the greater or less work which sooner or later is cast upon them. It may be particularly pointed out that cavities situated behind the one primarily implicated tend sooner or later to share in its hypertrophy and dilatation; that in cases of incompetence of either of the auriculo-ventricular orifices the corresponding ventricle, in consequence of receiving more than its due amount of blood, and of thus having more work thrown upon it, undergoes dilatation and hypertrophy; and that in obstructive disease of these orifices the ventricles tend to become atrophied from having less work to do.

Acute dilatation which occurs temporarily in acute febrile disorders, such as typhus, is due mainly to enfeeblement of the cardiac walls, but in scarlet fever is partly referable to high arterial tension. See SCARLET FEVER; and RHEUMATISM, ACUTE.

ANATOMICAL CHARACTERS.—In pure dilatation of the heart, the cardiac walls must be thinner than natural. It is a question, however, whether, excepting in the cases of partial dilatation or aneurysm and acute failure, dilatation ever takes place independently of hypertrophy; for even as regards the auricles, where dilatation with attenuation is chiefly observed, there is reason to believe that the attenuation is not commensurate with the extension which accompanies it, and consequently that the total bulk of muscular tissue is increased. When dilatation is associated with no apparent change in the thickness of the walls, hypertrophy is of course present.

It must be mentioned, however, that it is often very difficult to determine on *post-mortem* examination the true relation between the thickness of the cardiac walls and the capacity of the cardiac cavities; for their apparent relation is largely dependent on the condition of the cavities as to systole or diastole at the moment of death; and on the state of the heart as to cadaveric changes at the time of *post-mortem* examination.

The form which the heart assumes in dilatation is the same as that which it assumes in hypertrophy; and indeed, as the two conditions are probably always associated, it is needless to endeavour to establish any distinction between them in this respect. If the dilatation be general, the form of the heart remains unchanged, but its size is uniformly augmented. If the left ventricle be mainly affected, the heart appears not only enlarged but elongated, the left ventricle taking more than its due share in the formation of the cardiac apex. If the right ventricle be specially implicated, the heart becomes enlarged in its transverse diameter; it is more rounded in its contour as seen from the front than it should be; and its apex is obtuse, and either bifid, from the fact that the apices of both ventricles take an equal share in the formation of the cardiac apex, or formed wholly by the right ventricle. If the auricles be dilated, they constitute large masses on both sides of the root of the aorta and pulmonary artery.

The walls of the dilated heart vary not only in thickness, but also in quality. Thus they may be preternaturally firm or preternaturally soft; they may be healthy in structure, or may present more or less degenerative change.

CONSEQUENCES OF DILATATION.—Dilatation of the ventricles, especially if it be considerable, is apt to disarrange the mechanism of the auriculo-ventricular valves. Even in mere temporary distension of the right ventricle a kind of safety-valve action of the tricuspid valve takes place, in consequence of which regurgitation of blood occurs from the ventricle into the auricle. Moreover, established dilatation of the right or left ventricle is liable to be attended by persistent regurgitation of blood through the corresponding auriculo-ventricular orifice. The defaulting valve under these circumstances has a natural aspect; but careful examination shows either that the orifice has undergone dilatation in company with the ventricle—the valve itself presenting no corresponding increase; or that there is a want of relation between the size of the muscular papillares and chordæ tendinæ on the one hand, and the capacity of the ventricle on the other, which interferes with the due closure of the valve.

It is obvious that if regurgitation becomes established, the usual consequences of regurgitation will presently ensue—namely, in connection with affection of the left side of the heart, dilatation and hypertrophy of the left auricle, and subsequently congestion of the lungs and pulmonary apoplexy; and in connection with affection of the right side of the heart, dilatation and hypertrophy of the right auricle, fulness of the systemic veins, anasarca, nutmeg liver, and congested, indurated kidneys. It is also obvious that, even if no regurgitant condition be developed, dilatation of the heart, which implies feebleness of heart and imperfect circulation, must ultimately induce the ordinary remote consequences of heart-disease. A further consequence of dilatation and other cardiac affections attended by feeble circulation is the formation of thrombi during life, both in the heart itself and in other parts of the vascular system. Dilatation of the left auricle may cause compression of the left bronchus.

SYMPTOMS.—Since dilatation of the heart rarely, if ever, exists alone, but is associated with hypertrophy, valve-disease, degenerations, and other conditions, it is almost impossible to make any definite statement with regard to the signs and symptoms by which its presence may be recognised. Still, there is no doubt that dilatation is one of the most important factors of heart-disease, clinically considered; and that its supervention materially affects the patient's condition and prospect of life. Dilatation, as a rule, implies weakness, and over-distension of the implicated cavities with blood, which probably never becomes sufficiently expelled.

The *physical signs* of dilatation are necessarily in many respects the same as those of hypertrophy. The præcordial dulness is increased in area—the extent and form of this area, and the situation of the apex-beat, being determined by the general size of the heart, and the relative dimensions of its component parts. In proportion, however, as residual dilatation preponderates over hypertrophy, the impulse of the heart becomes weak, and possibly to some extent diffused. In extreme dilatation, as in extreme weakness from other causes, the sounds of the heart, and especially the first sound, are enfeebled. And it may be asserted that generally the tendency of dilatation is to shorten the first sound, and to give it the characters of the second sound. It has, nevertheless, been observed over and over again that it is in the concurrence of

hypertrophy and dilatation that the cardiac sounds attain their greatest intensity. The feebleness of the heart's action in residual dilatation is generally attended before long by more or less irregularity; and even in the absence of valve-disease, a mitral or tricuspid systolic murmur, implying regurgitation, is apt to be established.

The *symptoms* of dilatation are to a large extent those of cardiac obstruction, and more especially of mitral disease. The patient complains of weight, oppression, or uneasiness in the cardiac region, with probably a sense of fluttering there, and of a tendency to sighing respiration. He becomes short-breathed, and may have extreme dyspnoea. His face is apt to become livid; his extremities cold and blue; and his pulse weak and irregular. Dilatation of the systemic veins arises sooner or later; and subsequently general anasarca, commencing in dependent parts, serous effusions, epigastric pulsation, pulsation of the veins in the neck, and of the liver, together with the other usual consequences of cardiac failure. The chief of these are—congestion of the lungs, with pulmonary apoplexy, cough, and expectoration of blood; congestion, enlargement and tenderness of the liver, with jaundice; and congestion of the kidneys, attended by the discharge of scanty, high-coloured, heavy urine, containing albumen and possibly blood. Other symptoms, referable to the nervous and digestive organs, which need not be enumerated here, are also liable to supervene.

The symptoms will vary, of course, according as the left or the right ventricle is mainly affected. In the former case we are liable to have at first irregularity and feebleness of pulse with tendency to faint; then pulmonary complications; and at a later period, symptoms referable to the systemic venous circulation. The latter case is one of considerable interest; because in a large number of instances it is, in its most marked form, a consequence of emphysema of the lungs, or of other analogous conditions, and moreover is apt to come on very rapidly. Under these circumstances, there is necessarily much dyspnoea, but the systemic venous and capillary systems speedily become overloaded; extreme cyanosis often develops rapidly; and, before long, all the other symptoms referable to disease of the right side of the heart become established: namely, pulsation of the veins in the neck, and of the liver; epigastric pulsation, general anasarca, dropsy of the serous cavities, with perhaps petechial extravasations, jaundice from nutmeg liver, and albuminuria from congestion of the kidneys.

PROGNOSIS.—There is no doubt that some degree of dilatation of the heart, and more especially of the right ventricle, may arise either from over-exertion, or from functional disturbances, and in connection with pulmonary disorders. But such dilatation is for the most part temporary or remediable; and only by continuance of its cause does it become established and a matter of serious importance. Dilatation from over-filling, as of the left ventricle in aortic incompetence, is a permanent condition and not necessarily of evil omen. In the same way there is no doubt that the residual dilatation which comes on in the course of structural disease of the heart or lungs, or of other structural diseases which influence the action of the heart, is remediable within certain limits by due attention to the conditions under which it arises. Nevertheless

it is certain that the presence of dilatation with failure of the heart in connection with other diseases, more especially those of the heart itself, lungs, or kidneys, is a grave source of danger; and that in the great majority of cases it is of fatal omen, aggravating the patient's distress, and hastening his death.

TREATMENT.—The treatment of dilatation of the heart merges in that of the other cardiac conditions with which it is associated, and in that of other diseases in the course of which it may have supervened. It may be stated, generally, however, that the treatment is that of cardiac debility, and of distension of the heart with blood. See HEART, Valves of, Diseases of.

The chief indications, therefore, are rest of mind and body; avoidance of exposure to cold and wet; the exhibition of ample, nutritious, and readily digestible solid food; due attention to the action of the bowels, kidneys, and skin; and the employment of medicines likely to regulate and strengthen the action of the heart. For the last purpose digitalis in sufficient doses at short intervals is universally acknowledged to be of great value. It is desirable to combine the digitalis with other diuretics, such as potassium acetate and scopolium, until the anasarca has been removed, and afterwards with iron or some vegetable tonic. Ammonia and other diffusible stimulants are often called for to relieve urgent distress, and are of great service. In cases where there is much lividity, and evidence of stagnation of blood in the right side of the heart, removal of blood by venesection or leeching will often prove of great service.

When the dilatation is due to pulmonary disease, this of course requires primary and especial treatment.

J. S. BRISTOWE.

J. MITCHELL BRUCE.

HEART, Displacements of.—Besides the displacements of the heart that occur as the result of developmental errors or of disease, there are certain changes of position which this organ undergoes in health. The most important of these physiological displacements of the heart are—first, its vertical movements in respiration; and, second, the alterations in its situation corresponding with changes in the bodily posture. The present article, however, will deal only with abnormal displacements of the heart.

I. Congenital Displacements.—Such misplacements may be either within the cavity of the thorax, or external to it.

1. Of the *internal* malpositions—*ectopia cordis intrathoracica* or *ectocardia intrathoracica*—the most common is that to which the term *dextrocardia* has been applied. In this the heart is in a very similar position on the right side of the chest to that which it should occupy on the left. This condition may co-exist with transposition of the other viscera of the body, or it may occur alone. When the heart is misplaced, the aorta generally follows an irregular course, crossing the right bronchus and passing down to the right side of the bodies of the vertebrae; and the right carotid and subclavian arteries are given off as separate vessels, while the brachiocephalic trunk is situated on the left side. In some instances, however, the vessels at the arch are not transposed; while in others the aorta, after passing over the right bronchus, crosses the spine and follows its usual course to the left of the bodies of the ver-

tebrae. In cases of transposition the heart itself may be well formed; or it may be very imperfectly developed.

In another kind of misplacement, *mesocardia*, the heart is situated more in the median line than natural—a position which it occupies in the fetus at the earlier periods. Cases have also been recorded in which the organ occupied a transverse and an antero-posterior direction.

2. Of the *external* misplacements, those in which the heart is situated externally to the thoracic cavity—*ectopia* or *ectocardia extrathoracica*—the most common is that in which, from deficiency of some part of the sternum, the organ lies in front of the chest—*ectopia cordis* or *ectocardia pectoralis*. In other cases, from deficiency in some portion of the diaphragm, the heart is placed in the abdomen, either lying in the peritoneal cavity, or, if the integuments are partially defective, in a sac in the præcordia—*ectopia cordis* or *ectocardia abdominalis*. In a third form the heart lies at the root of the neck—*ectopia cordis* or *ectocardia cephalica*.

SYMPTOMS, DURATION, AND TERMINATIONS.—When the heart is well formed, its malposition within the thorax does not necessarily cause such interference with its functions as to be productive of symptoms, or materially to curtail the duration of life. Indeed, cases are on record in which the heart and other viscera have been transposed in persons who had never presented any signs of disorder of the circulation, and who lived to very advanced ages. When, however, the organ is also defective, and especially when the displacement is external to the thoracic cavity, life is usually only of short duration—though some remarkable cases of external displacements are on record, in which the patients survived to advanced ages.

II. Acquired Displacements.—**ÆTIOLOGY.** The causes of acquired displacement of the heart may be arranged in two classes—namely (1) conditions that exert *pressure*, and (2) conditions that exercise *traction*, upon the heart.

1. The heart is *pressed* or pushed out of position by effusions of fluid—inflammatory, dropsical, or bloody—into either pleural cavity; by pneumothorax of either side; by intrathoracic tumours—whether mediastinal (including aneurysm and abscess), pulmonary, or parietal; by hypertrophic emphysema, or other causes of enlargement of the lungs; by extensive pneumonic consolidation; or by abundant pericardial effusion of any kind. Certain conditions of the abdominal contents produce a similar effect—for example: gaseous distension of the stomach and intestines; enlargement of the liver and other solid organs; abdominal tumours of all kinds; the pregnant uterus; and ascites, when considerable. Hernia of the abdominal viscera through the diaphragm, and abscesses in relation with the diaphragm, also cause displacement of the heart.

2. The heart suffers *traction*, or is drawn out of position, during absorption of pleuritic effusion with imperfect expansion of the lung, on either side; by the contraction of pleuro-pericardial adhesions; of pulmonary cirrhosis, or of cavities in phthisis; in collapse of either lung from pressure on the main bronchus; and in some forms of deformity of the chest from curvature of the spine.

MECHANISM OF DISPLACEMENT.—When the displacing force belongs to the first or pressure-class, it acts against the surface of the pericardium and heart that is opposed to it, and presses or pushes it

a tergo, away from its own seat, in the direction of least resistance. Thus the heart is, speaking broadly, pushed towards the left by effusion into the right pleural cavity; towards the right by similar disease on the left side; downwards by tumours in the region of the base; and upwards by gaseous distension of the stomach.

On the other hand, when the displacing force is of the nature of traction, the heart is drawn *a fronte*, that is, towards the seat of the force. Thus, when a cavity in a tuberculous lung is contracting, the pericardium and heart, as well as the walls of the chest, are displaced towards the healing area. It must be observed, however, that in this class of cases, actual traction, in the strict sense, is rare, and that the ordinary displacing force is, in reality, the atmospheric pressure; the heart and the other organs being 'sucked' towards the potential vacuum, in the same way as water is 'drawn' into a syringe. Still, in a very small number of cases, the pericardium does actually become involved in a healing process in the lungs; and it and the heart are dragged towards the cicatrix.

Besides the displacing force, there are at work in dislocation of the heart certain other agencies, which contribute to the result, whether their effect be to increase or to diminish that of the chief cause:—

(a) The weight of the heart manifestly favours displacement in different directions, according to the posture. Thus, in the erect posture, it favours downward and limits upward displacement. However, the effect of the weight of the heart is comparatively insignificant, and may be practically disregarded.

(b) The resistance, positive or negative, of neighbouring parts must be taken into account. The heart when disturbed from its position will move in the direction of least resistance. Thus it cannot be displaced to any extent either forwards or backwards, but is moved with comparative ease towards either pleural cavity. The resistance inferiorly is greater under the right half of the diaphragm than under the left. On the other hand, the resistance around may become negative; for example, in left pleural effusion the corresponding half of the diaphragm is pushed downwards, and the accompanying downward displacement of the cardiac apex is thus increased.

(c) The heart is attached at its root; and, speaking broadly, this is a fixed point, at the right and upper extremity of the long cardiac axis. This attachment will limit and otherwise modify displacements of the heart in all directions, especially downwards. Round this point as a centre, and with the long axis as the radius, the apex of the heart would describe an arc of a circle, cutting the surface of the chest in the left axilla, the left submammary region and the epigastrium.

(d) The tendency that the heart has to rotate or roll on one or other of its axes is also affected by its attachment at the root. If the heart lay free in the pericardial cavity, there would be no limit to such rotation under the influence of pressure or of traction. The base being fixed, rotation is greatly limited, and does not occur to any extent except around the longitudinal axis; the left ventricle, for example, being rotated more forwards or more backwards, as the case may be. Rotation round the transverse-horizontal and the antero-posterior-horizontal axes is very limited.

ANATOMICAL CHARACTERS AND EFFECTS. — The

only essential change that the heart is found to have undergone in displacement is an alteration of its relations to the surrounding parts. The softer parts of the cardiac wall, however, such as the auricles, are sometimes compressed to a moderate degree. The pericardium is partly dislocated and partly stretched. The great vessels at the base of the heart and at the root of the neck may be elongated, shortened, twisted or bent, according to the particular form of displacement; and the circulation within them impeded. The neighbouring organs are variously displaced and compressed. One of the effects often seen after displacement is permanent fixation of the pericardium and heart in their new position, for example, in the pleural cavity, on the disappearance of the original cause.

The effects of displacement of the heart upon its functions differ greatly in the two classes of dislocation to which we have referred:—

In displacement due to *pressure*, the heart is compressed between the displacing force and the resistance in other directions, and the dislocation is generally rapid. Fortunately, in most cases of such displacement the resistance is slight; and the heart, if healthy, suffers little or no real compression of its substance or cavities between the two forces, the mobile and compressible lung especially yielding before it. But if the heart be diseased—and especially if its walls be weak, degenerated or dilated—moderate compression, as in flatulence, may cause embarrassment of the cardiac action and even fatal paralysis; and the rapidity or even suddenness with which displacement generally occurs when due to pressure—for example, in pneumothorax—is another and perhaps the principal cause of such embarrassment.

On the other hand, when the heart is *drawn* out of its normal situation towards a tubercular cavity, or towards either pleural cavity from which an inflammatory effusion is being absorbed, the displacement occurs, not because there is want of space, but because there is excess of space, within the thorax. The process is also very gradual. The effects, therefore, upon the functional activity of the heart may be said to be few, though the unusual pulsation may be a source of inconvenience, and even of anxiety, to the patient. In very rare cases, the heart and pericardium, when thus displaced, may be involved in the fibrotic process going on in the lung or pleura, and the adhesions thus established may ultimately interfere with the cardiac action.

SYMPTOMS.—In displacement of the heart, special symptoms are frequently slight or altogether wanting; or they are inseparable from the symptoms of the original cause. This may be said to be almost invariably the case when the displacement is due to gradual traction, as in phthisis. In the pressure class of cases, on the contrary, there are frequently developed, and that rapidly or suddenly, symptoms due to compression of the heart, such as a sense of distress, stifling, and pain over the præcordia or at the epigastrium, or even true angina; dyspnoea, perhaps amounting to orthopnoea; palpitation; blueness of the surface; and irregularity and feebleness of the pulse. When the displacement is due to upward pressure from gaseous distension of the stomach and intestines, the above symptoms may be associated with flatulence or 'spasms,' and are relieved by the erect posture, eructation, vomiting, and the administration of carminative and absorbent remedies. If this condition be not removed within

a short time, it may become aggravated, pass into a state of collapse, and end in death.

VARIETIES AND PHYSICAL SIGNS.—The varieties of cardiac displacement, according to the direction in which the dislocation occurs, may, for clinical purposes, be said to be as follows: towards the *left*, towards the *right*, *downwards*, *upwards*, *backwards*, and *forwards*. It must be observed, however, that this is only a broad general classification, and that the heart is very rarely displaced in an absolutely horizontal, or in an absolutely vertical plane. The exact direction taken in each variety will now be described, as well as its special causes, and the physical signs by which it may be recognised.

1. Displacement towards the Left.—This, the commonest variety of marked cardiac dislocation, is most frequently caused by contraction of the left lung from any of the conditions already enumerated, and by effusions into the right pleural cavity. Right pneumothorax, and tumours connected with the right side of the chest, with the mediastinum, or with the right lobe of the liver, are less common conditions leading to the same result. The distance towards the left to which the heart is dislocated varies, the extreme limit being probably the anterior axillary line. During its progress towards the left, the heart is rotated around its longitudinal axis, so that the right ventricle is more exposed anteriorly; and the apex is moved, at first somewhat downwards, and afterwards upwards.

The visible and palpable impulse is found to the left of its normal situation, and either lower or higher than it, or on the same level with it, according to the degree of displacement. In some cases due to contraction of the left lung, the impulse may be found in any one or in all of the left intercostal spaces from the base to the apex of the heart, and of different rhythm in the different spaces. If the displaced heart be the seat of valvular disease, a thrill may be felt in an unusual situation, for example, in the left axilla. The area of percussion-dulness is altered in outline, being invaded on the right side either by the dulness due to effusion there, or by resonance due to pneumothorax or to encroachment of the right lung-border; while it is either transposed towards the left axilla, or blended with unnatural dulness over the left lung. The cardiac sounds are reduced in loudness over the normal præcordia, while they are unnaturally loud towards the left axilla. Structural murmurs if present are similarly affected, as regards the seat of their greatest intensity and the lines of their conduction. A systolic murmur may be developed at the base of the heart from distortion of the great vessels.

2. Displacement towards the Right.—This form of dislocation of the heart is the result of effusion into the left pleural cavity; of contracting processes connected with the right lung or pleura; of left pneumothorax; and of tumours of the left side of the chest or in the mediastinum. The heart may be displaced towards the right side until an impulse is found in the axillary region, but the true apex at the same time is transferred only as far as the epigastrium. During its lateral movement, the heart is rotated on its longitudinal axis in such a manner that the left ventricle is more exposed.

The physical signs correspond closely with those enumerated under left displacement—the two sides being, of course, exactly reversed. The cardiac impulse is most frequently transferred to the epigas-

trium. New areas of pulsation are developed in the region of the right nipple, and in the second and third right interspaces, close to the sternum; they indicate the displaced position of the right auricle, if præ systolic, or of the aorta, if systolic and followed by palpable shock in diastole. The description of the auscultatory phenomena, as regards both sounds and murmurs, does not require to be repeated.

3. Displacement Downwards.—This is an exceedingly common form of cardiac displacement, though seldom extreme in degree. It is the constant result of hypertrophic emphysema of the lungs; and may also be caused by the downward pressure of tumours at the base of the heart, such as aneurysm, and by collapse of the stomach and intestines. Displacement of the heart downwards is limited by the diaphragm, and by the attachment of the pericardium and great vessels at the root of the heart. At the same time the apex may either move somewhat towards the left in its descent if the downward pressure be uniform, as in emphysema; or it may ascend somewhat towards the left if the pressure be exerted chiefly upon the base.

The ordinary apex-beat is generally quite imperceptible in this form of displacement, on account of enlargement of the lungs; or it is greatly weakened, and situated in the sixth left space, or lower, to the left of its normal position. A new area of systolic pulsation is perceptible in the epigastrium, generally well marked, and connected with the right ventricle. The præcordial dulness is usually completely replaced by pulmonary resonance; or, more rarely, confused by the dulness of some form of mediastinal tumour. The cardiac sounds are feeble, or absent, over their usual seat; and are heard, instead, over the epigastric triangle and the lower left cartilages.

4. Displacement Upwards.—The many abdominal causes of this form have been already mentioned; so have the symptoms due to compression of the heart which characterise it when so produced. The heart, as a whole, is moved upwards in the chest, and at the same time the apex passes more or less towards the left, and the right ventricle may become somewhat more exposed anteriorly.

The cardiac impulse is elevated until it is found on the nipple-level, or even higher; or it is lost, along with the area of percussion-dulness, behind the inferior border of the left lung. The sounds of the heart are transposed upwards, and weakened. The displacement of the cardiac apex towards the left axilla in pericardial effusion is described elsewhere. See PERICARDIUM, Diseases of.

5. Displacement Backwards.—This variety of displacement of the heart is very uncommon; and when it does occur, is generally referable either to abundant pericardial effusion, or to backward curvature of the spine (kyphosis) in the dorsal region. A certain amount of backward displacement is, however, not very rare in extensive excavation of the left lung, in association with other forms of dislocation. The base of the heart is then the part most transposed into the left paraspinal groove, and the apex is tilted somewhat forwards as well as elevated.

The physical signs of backward displacement are those of the cause of the malposition rather than any that can be referred to the condition itself.

6. Displacement Forwards.—Displacement forwards is also very rare, although it is frequently simulated by bulging of the præcordia in enlarge-

ment of the heart. The chief cause of it is the presence of a tumour in the mediastinum—especially aneurysm of the descending aorta, or enlargement of the bronchial glands. The amount of actual transposition is necessarily exceedingly small, the anterior border of the lungs being compressed or pushed aside, but the further progress of the heart forwards arrested by the anterior wall of the chest.

The physical signs are, therefore, increase of the area and strength of pulsation and of percussion-dulness over the præcordia, bulging of the same in young subjects, and increased loudness of the cardiac sounds in that situation.

7. Complex Displacements.—It has already been indicated that displacements of the heart, strictly speaking, occur almost without exception in more than one of the directions described; and they may all, therefore, be said to be generally more or less complex. Dislocation at once upwards and towards either side is especially common, as the result of contracting processes in the apex of the lung.

DIAGNOSIS.—After the full account that has been given of the several forms of displacement of the heart, there ought to be no great difficulty in diagnosing them from each other, as well as from the conditions which simulate them. These must be carefully remembered. The chief of them are: (1) physiological displacements, already referred to; (2) cardiac enlargement, especially when attended with bulging of the præcordia; (3) pulsating tumours of the chest and abdomen, particularly aneurysm of the aorta; (4) adhesion of the pericardium; and (5) atrophy of the lungs from any cause.

TREATMENT.—The rational treatment of displacement of the heart would be to remove its cause; but when the cause is of the nature of traction, treatment is very rarely called for, even if it were possible. In displacement due to pressure, on the contrary, treatment is often urgently indicated, perfectly practicable, and highly successful by attention to the cause. The unpleasant sensation of pulsation complained of in some instances of displacement—for example, in phthisis—is frequently relieved by an assurance on the part of the physician that the palpitation is of no import; and by the application of a simple plaster, containing iron, belladonna, or opium. J. MITCHELL BRUCE.

HEART, Failure of.—See **HEART, Dilatation of**.

HEART, Fatty Accumulation on.—**SYNON.** : Fr. *Hypertrophie graisseuse du Cœur*; Ger. *Fettige Infiltration des Herzens*.

DEFINITION.—The growth of fat on the surface and in the substance of the heart, in quantity sufficient to interfere with its functions, and thus to constitute a disease.

ETIOLOGY.—Whenever excessive quantities of fat are deposited in the subcutaneous tissue and other usual sites, the sub-epicardial tissue is also likely to become the seat of an excessive accumulation (see **OBESITY**). It is therefore a disease of late middle life, the majority of cases being over fifty years of age.

MORBID ANATOMY.—The accumulation is always most marked in the places where fat is normally

present—i.e. the track of the coronary arteries and their branches; thence it spreads until, in extreme cases, the muscular walls of the right ventricle may be entirely concealed by a thick layer of fat, though the left ventricle is rarely, if ever, completely covered. When the fat has accumulated to this extent the walls of the heart lose all appearance of muscular structure, looking like a thick layer of adipose tissue. Near the surface, on microscopical examination, but few muscular fibres can be seen, and the very wide intervals between them are occupied by fat-cells (see fig. 1). Proceeding inwards, the fat-cells become fewer, and finally disappear before the endocardium is reached. It is worthy of note that the fibres, though surrounded by fat, may still retain their normal structure. Fatty degeneration, however, often co-exists with fatty accumulation.

FIG. 1.—Fatty growth in the substance of the heart. $\times 400$ diam.

SYMPTOMS.—The fat accumulated on the heart and in its substance has no action unless present in sufficient quantity to affect the nutrition and therefore the contraction of the muscular fibres among which it lies. The feeble circulation and easily induced dyspnoea often found in obese persons are perhaps occasionally attributable to the presence of the fat over the heart; but in the majority of cases the presence of the fat is an indication of the diminished functional activity of the heart rather than the cause of it. A heart affected in this way is more prone to rupture.

The presence of fatty accumulation on the heart may be suspected in an obese person when the pulse is small and weak, when the first sound of the heart is feeble and the impulse weak, and when the extent of dulness on percussion is increased. It is probable, however, that in many of these cases fatty degeneration of the muscular fibres is also present.

TREATMENT.—The treatment of fatty accumulation on the heart is identical with that of its cause, obesity. See **OBESITY**.

If the symptoms above mentioned are present, especial care must be taken not to put any excessive work upon the heart, but by tonics, passive movements, massage, and the promotion of free excretion to aid in the restoration of the normal strength of the organ. H. MONTAGUE MURRAY.

HEART, Fatty Degeneration of.—**SYNON.** : Fr. *Dégénérescence graisseuse du Cœur*; Ger. *Fettige Metamorphose des Herzens*.

DEFINITION.—A pathological process in which the muscular fibres of the heart are converted into a granular fatty matter.

ÆTIOLOGY AND PATHOLOGY.—The process by which this change takes place, as well as the circumstances under which it occurs, is discussed under the head of FATTY DEGENERATION.

This change is best seen in cases in which the orifices of the coronary arteries are contracted or where there is thickening or calcification of one of the trunks or of the branches of these vessels as a result of syphilis, strain, chronic nephritis and, other causes of arterial degeneration (*see* ARTERIO-SCLEROSIS). The fatty change is found to occur in the more *diffused* or *general* form in those diseases in which the vital powers are lowered, as in chronic cachectic disease, pernicious anæmia, poisoning by phosphorus and chronic alcoholism, and after loss of blood. In the acute specific fevers and septic diseases the tissue of the heart also undergoes this change. A more or less diffused form of fatty degeneration takes place in cases of enlarged heart, since these enlarged hearts require a larger supply of the materials for nutrition than can be furnished to them by the coronary arteries, which in such cases are frequently themselves diseased, both at their origin and in their course. The disease also occurs after delivery in some instances, the heart having been enlarged during pregnancy; and certain cases of sudden death after parturition are thus explained. The disease is more frequent in males, in the proportion of nearly two to one.

ANATOMICAL CHARACTERS.—In fatty degeneration the heart is enlarged in about two-thirds of the cases. Not infrequently it is simply dilated; but it may be of average size, or even below the normal. The colour of the heart's substance is pale; generally it is of a yellowish-brown or buff, or muddy pink colour. This discolouration is seen in spots or patches; and though the whole heart may be pale, the spots, being still paler when seen beneath the endocardium, give the tissue a mottled look. The same appearance may be observed beneath the pericardium, and in the substance of the heart. With the progress of disease the spots run together, giving portions of the walls a uniform buff-coloured character, while the rest of the organ retains its ordinary aspect. The consistence varies from that of mere flabbiness or softness, to such a condition as permits of the tissue being torn like wet brown-paper. The organ then feels like a piece of wet chamois-leather, or a wet glove. In other cases the heart retains in appearance much of its ordinary colour, but the tissue breaks down on pressure, as does a lung consolidated by pneumonia. This is a state which occurs more frequently in hearts which are hypertrophied.

All parts of the heart are subject to fatty degeneration, but not equally so. It is most frequently found in the left ventricle; next in the right ventricle; then in the right auricle; and least frequently in the left auricle. It is generally more evident in the columnæ carneæ, and in the inner layers of the muscular walls, than elsewhere.

The *microscopical characters* of this disease are described in the article on FATTY DEGENERATION. The effects on the heart of fatty degeneration include *rupture* (in twenty-five out of sixty-eight cases); and partial rupture, leading to effusion of blood into the walls ('*cardiac apoplexy*'), cyst-formation, and false aneurysm of the heart. The last

may also form by simple yielding of a portion of the softened cardiac wall. The involvement of the columnæ carneæ sometimes leads to imperfect action of the valves; but valvular disease itself is not often present in this connection, and when the valves are affected it is chiefly the aortic valves that are involved.

SYMPTOMS AND DIAGNOSIS.—There is no doubt that many cases occur in which fatty degeneration is found in the heart after death, without its presence during life having been suspected, particularly in exhausting disease of which it simply forms a part. In such cases the requirements of the system may not be out of proportion to the powers of the heart; death then comes on slowly and insidiously without attention being attracted to the state of this organ. On the other hand, when the heart suffers from some local cause, such as disease of the coronary arteries, while the system generally maintains its powers more or less fully, the balance between it and the heart is lost, and evidence of the change that has occurred in the central organ of circulation can be traced without difficulty. Among the symptoms of the disease we then observe faintness and syncope, disordered respiration, pain in the region of the heart, disturbed pulsation, drowsiness, and coma. The patient complains in the earlier stages of being easily exhausted, particularly by mounting ascents; he says he feels faint on reaching the top of a flight of stairs; though not giddy, he feels he must fall; though not breathless or fainting, he sighs deeply and seeks the air. Any unusual excitement, or a heated or close atmosphere, produces the like effects. At the same time there is often experienced an uncomfortable sensation of choking or fulness in the chest. In the intervals the patient may be fairly well.

Of the effects of fatty degeneration upon the functions of the heart, the most prominent are those which exhibit the weakness of the organ. *Coma*, preceded or not by giddiness, is a striking symptom. Adams of Dublin mentioned as many as twenty attacks in one of his cases of fatty heart; and Quain noticed the occurrence of even more frequent seizures. The term '*cardiac syncope*' may be well applied to the condition of faintness which is frequently found in connection with fatty heart. In some cases the feeling of syncope amounts to little more than a simple sense of faintness—that the patient must fall if he do not lay hold of something. In other instances it is accompanied by a feeling of impending death; and such patients do frequently die. Death may result in such cases from cardiac failure, as indicated after death by a flabby heart containing blood in the left ventricle; or, where there is a less amount of degeneration, death may result from irregular action or spasm, and the ventricles may be found empty.

Præcordial pain is also an effect of fatty degeneration. It may occur independently of syncope; its association with syncope constitutes what is called *syncope anginosa*. *See* ANGINA PECTORIS.

The *respiration* is always affected in cases of fatty degeneration, the result being either simple breathlessness, even on slight exertion, or Cheyne-Stokes respiration. In some instances the disturbance is represented as a sense of choking or suffocation; the person feels as if he were breathing through a sponge. In some instances it is so slight as scarcely to be regarded; in others so severe that the smallest effort, particularly in mounting ascents,

is most painful. In Cheyne-Stokes respiration there is usually no change in the heart's action; but during the phase of dyspnoea, the heart's action has been observed to become remarkably irregular.

As the disease advances, the attacks, of whatever kind, become more frequent and severe, and often disturb and distress the patient at night. The temper becomes irritable; the expression frequently appears anxious, and the countenance sallow. Copious perspiration from very slight causes, coldness of the extremities and swelling of the ankles, are among the further incidents of the disease. The pulse is generally affected; but its characters depend upon the part of the heart affected, and on the extent and degree of the disease. Intermittence and irregularity are the more frequent alterations; weakness is another; and infrequency—often remarkable—is a third. Rapid pulse, more especially when it increases with age, is a symptom deserving attention in the diagnosis of fatty degeneration. The irregularity may be constant, or it may appear and disappear: it will be present during the slight disturbances above described, disappear altogether when the patient is in tolerable health, and return as the effect of any depressing cause—a striking observation, because the cause is insufficient to affect a sound heart. Still, the frequency with which the pulse is affected in cases of simple dyspepsia, more especially along with the gouty diathesis, should not be overlooked in the diagnosis of fatty heart.

It was formerly thought that the presence of *arcus senilis* was characteristic of this disease, but this view is now generally discarded. See *ARCUS SENILIS*.

As the disease progresses the symptoms become more marked; the various effects of feeble and languid circulation further show themselves; angina may perhaps become fully developed; or the patient may be cut off suddenly by one or other of the effects connected either immediately or remotely with the lesion itself. Of 83 cases of 'fatty disease' of the heart collected by Quain, 68 had died suddenly.

The *physical signs* that characterise fatty disease are neither many nor marked. They are—a feeble præcordial impulse, proportionate to the extent and the degree of the disease; a feeble muffled first sound, under like conditions, sometimes scarcely audible. When the heart is enlarged, the impulse, though weak, will be found extended, and so likewise will be the dulness on percussion. A murmur may be present, from degeneration of the columnæ carneæ, as suggested by Rokitsansky. The second sound is often distinct and clearly accentuated, as compared with the first.

DIAGNOSIS.—When the heart is hypertrophied or dilated only, the presence of fatty degeneration is more difficult of diagnosis by its physical signs. We must then seek to trace how far the usually well-marked signs of hypertrophy of the organ are modified by those we have described as being present in, and characteristic of, fatty degeneration. The same observations will apply to dilatation. The symptoms and signs of fatty degeneration might be confused with like phenomena originating in disordered state of other organs, such as the lungs or liver.

PROGRESS, DURATION, AND TERMINATIONS.—It is impossible to determine the duration of a disease the date of origin of which is in most cases very obscure. Still there are grounds for

believing that persons with a certain amount of degenerated tissue in their hearts have lived for many years. On the other hand, death has occurred from fatty degeneration of the heart, determined *post mortem*, in which the entire absence of symptoms until a few months before the fatal event justified the opinion that the duration of the disease had not much exceeded that period. When fatty degeneration occurs as the result of phosphorus-poisoning or of certain exhausting diseases, the progress of the change, which can then be determined, is rapid. In such cases, the morbid process is not confined to the heart alone, and therefore death, when it occurs, cannot well be attributed solely to the condition of this organ.

Death is frequently sudden, the proportion being as five to one compared with other modes of death from fatty disease of the heart. The immediate modes of death in these cases are those already alluded to, namely, by syncope, angina, coma, and rupture of the heart; the first and last of these contributing nearly the whole number of those who die suddenly.

PROGNOSIS.—In cases where the disease depends on toxic causes, as in phosphorus-poisoning, and in cases where it is of the nature of involution—for example, after parturition—there is good ground for believing that, the cause being removed, the effect will cease, and a fairly healthy condition of the organ be restored. On the other hand, when the coronary arteries are obstructed, or when nutrition generally is impaired, the prognosis must be in the highest degree unfavourable, more especially so if in the latter case the patient cannot be placed in a condition by which this degenerative tendency may be counteracted.

TREATMENT.—The treatment consists in the adoption of all the measures calculated to improve the general health—such as pure fresh air, wholesome food and temperance, together with moderate exercise (either driving, riding, or walking), if it can be accomplished without causing pain or breathlessness. Everything which might tend to lay stress on the heart's action, such as walking uphill or making efforts, or any mental excitement, should be avoided. With reference to drugs, such tonics as can best be tolerated by the patient should be given, especially iron and strychnine. Special attention must be paid to the condition of the excretory organs, such as the kidneys and liver, which are liable to become congested when the cardiac action is feeble. In cases of actual syncope, in addition to the administration of the usual stimulants, galvanism applied from the nape to the præcordia by the interrupted current has in a few instances been useful.

It must also be remembered, with reference to the administration of anæsthetics, that chloroform has an especially depressing effect on the action of the heart; and that when its power is enfeebled by fatty degeneration, a very small quantity of this anæsthetic, which would have little or no effect on a healthy heart, may prove fatal.

RICHARD QUAIN.

J. MITCHELL BRUCE.

HEART, Fibroid Disease of.—**SYNON.** : Chronic Myocarditis.

DEFINITION.—A morbid condition in which some of the muscular fibres of the walls of the heart are replaced by fibrous tissue.

ÆTIOLOGY.—Fibroid disease of the heart is met with most frequently in middle-aged male subjects. The disease is supposed to be occasionally nothing more than an extension between the muscular bundles of a chronic process that has commenced as endocarditis or pericarditis. The cause of this, which is generally rheumatism, is then regarded as the cause of the fibroid growth; but more probably the serous inflammation is the result of the fibroid change. Fibrosis is sometimes the consequence of acute interstitial myocarditis. In a considerable number of cases of fibroid disease, the change is syphilitic. In other instances it is associated with degenerative changes in the vessels, myomalacia cordis, or infarction. A general increase of fibrous tissue in the myocardium may also be the result of prolonged congestion of the coronary veins (*see* HEART, Congestion of). Very frequently no cause can be discovered.

ANATOMICAL CHARACTERS.—Fibroid disease of the heart occurs most frequently in the walls of the ventricles. In rare instances there is a uniform increase of fibrous tissue between the muscular fibres throughout the organ. In other cases the disease appears as a local thickening of the connective tissue underneath an opacity of the endocardium or of the pericardium, whence septa run outwards or inwards between the muscular bundles. Most frequently, however, it presents the appearance of a *fibrous patch*, generally situated near the apex of the heart, replacing the muscular substance throughout its whole thickness, and, in some cases, even involving a considerable portion of one ventricle. Smaller patches, nodules, scars, and streaks may be found in the deeper parts of the myocardium. The apices of the papillary muscles, again, may become fibroid, especially in chronic valvular disease. Polypoid *tumours*, composed of fibrous tissue, have been met with on the endocardial surface of the heart, more especially projecting from the wall of the left auricle. Possibly the detachment of such a polypus may be one mode of origin of the 'fibrinous balls' or 'concretions' occasionally found lying free in the auricular cavities. Fibroid formations due to *syphilis* are described in the article on HEART, Syphilis of.

Microscopically the appearances are seen to be due to the presence of dense fibrous tissue. *See* FIBROSIS.

If a large portion of the wall of one cavity is fibrotic, irregular patchy dilatation of the chamber ensues. Localised fibrosis, especially if it commences beneath the endocardium, gives rise to chronic aneurysm of the heart, by the yielding of the diseased area to the intra-ventricular pressure (*see* HEART, Aneurysm of). Deeper or more limited patches or lines of cirrhosis cause irregularity or puckering of the cardiac walls; and valvular insufficiency may result from this, or from fibrosis and functional disturbance of the papillary muscles. Lastly, fibroid disease occasionally involves the conus arteriosus in an annular form, giving rise to constriction and the formation of so-called 'cardiac stenosis.'

SYMPTOMS.—The symptoms of fibroid disease of the heart vary greatly. When the fibrosis is very limited, few symptoms are present. In a majority of the cases in which a considerable portion of the cardiac wall has been found diseased, the symptoms were described as those of failure or dilatation of the heart, namely, dyspnoea on exertion; præ-

cordial pain or distress; occasional palpitation; a small, weak, or irregular pulse; dropsy; and visceral complications. As a rule, no endocardial murmur had been present; but fibrosis of the papillary muscles had sometimes given rise to signs of incompetence of the auriculo-ventricular valves. *See* also HEART, Aneurysm of; and HEART, Syphilis of.

COURSE AND TERMINATIONS.—The course of fibroid disease of the heart is generally chronic, although urgent symptoms may be observed a short time before death. Attacks of pain, palpitation, and dyspnoea may occur and subside long before the fatal illness. The development of cardiac aneurysm, and its possible terminations, will modify the course of the disease. Sudden death may occur, with or without previous cardiac symptoms, and must be regarded as a special mode of termination of fibroid disease of the heart. Otherwise the cases generally end by pulmonary complications, dropsy, and exhaustion.

DIAGNOSIS.—Fibroid disease of the myocardium has to be diagnosed from chronic valvular disease; from enlargements due to extracardiac causes, such as renal disease, gout, or emphysema; and from fatty degeneration. Its existence is suggested by a history or other evidence of syphilis. Under all circumstances, an accurate diagnosis is extremely difficult, if not impossible. The presence of a murmur does not exclude fibrosis, as the valves may become secondarily involved; and valvular disease is not always attended by a murmur. The other cardiac lesions mentioned must be excluded in the ordinary way.

PROGNOSIS.—When fibroid disease of the heart is accompanied by symptoms sufficient to establish a diagnosis, the prognosis is unfavourable, although it is not necessarily rapidly fatal.

TREATMENT.—This consists in relieving and supporting the heart by every possible means, especially rest and cardiac stimulants, such as alcohol and ether. Potassium iodide may be given with benefit in some cases, particularly if there be a history of syphilis. Digitalis will have to be administered with great circumspection.

J. MITCHELL BRUCE.

HEART, Functional Disorders of.—**DEFINITION.**—A disturbance in the functions of the heart, with or without pain, having origin in causes other than inflammation or organic diseases of the heart itself.

Functional disorders may co-exist with organic disease, but only functional disorder, uncomplicated with organic lesion, will be considered in this article.

ÆTIOLOGY.—To estimate the *immediate* or *proximate* cause of functional disturbance of the heart, regard must be had to its structure, innervation, and blood-supply. Weak muscular fibre, apart from degenerations by disease, becomes a predisposing cause of feeble and irregular action. Interference with the functions of the cardiac ganglia, the vagus nerve, and the nerves and ganglia of the sympathetic system may so modify the action of the heart as to cause deficiencies of power of every variety and extent. Any abnormal condition of the blood-supply, whether in quantity or quality, shows itself by disturbance in the functions of the heart. The causes of functional disorder may be classified thus: (1) Those conditions acting through or upon the nervous system, such as the general exhaustion of

the nervous system; all forms of reflex irritation arising from dyspepsia or diseases of lungs, liver, kidneys, uterus, and other viscera; venereal excesses; mental excitement, shock, or distress; protracted, violent, and unusual physical exertion, especially cycling, running, and rowing; acute fevers; chronic diarrhoea; various articles of diet, as tea and coffee; alcohol and tobacco in excess; many medicines, as aconite, belladonna, and digitalis; fasting and prolonged exposure to cold; and injuries, notably blows on the epigastrium. (2) Those conditions acting upon the general blood-supply of the body, and consequently affecting the special blood-supply of the heart, such as the turgid and plethoric states of gross feeders, depraved states caused by bad and deficient diet, and all forms of blood-disorder, as anaemia, gout, and scurvy.

Females are on the whole more subject to functional disorders of the heart than males. These disorders most usually occur between puberty and the age of thirty, but they may be met with at any period of life.

SYMPTOMS.—In the simplest form of functional disorder there is a morbid consciousness of the heart's action. The patient complains of throbbing, fluttering and palpitation, to which in some cases may be added throbbing of the vessels in the neck, noises in the ears, and flushing of the face. In some of these cases examination may show a healthy and normally acting heart. In other cases, there is rapidity of action with or without irregularity, and to the symptoms mentioned may be added heat and pain in the head, with a sensation of a whizzing, or rushing upwards of the sounds of the heart; dimness of vision, with photophobia; and a tendency to syncope, and to clammy perspirations, with cold shivering; and after the attack a large amount of pale urine may be voided. In some rare cases the voluntary muscles, more especially of the lower extremities, may refuse to act, so that the gait becomes tottering, or the patient grasps adjacent objects to steady himself, yet there is neither paralysis nor vertigo. The irregular form of nervous palpitating heart is often associated with anaemia or that general enfeeblement of the body-powers denoted by the term neurasthenia.

Sometimes the principal symptoms are anxiety and lowness of spirits, with mental and bodily incapacity for exertion; flatulent dyspepsia, with cold clammy extremities; anorexia, or perverted appetite; exhaustion, with tendency to faintness; and there may be a sensation of præcordial pain. Males are more subject to this form of functional disorder than females, and it chiefly occurs in persons having an abnormally small and feeble heart, or in whom a state of general nervous debility is superimposed.

When the distinctive feature of functional disorder is rhythmical error, and this is appreciable to the patient, the special symptom is that of extreme anxiety, even to the fear of impending death. Such forms of disorder occur in those having weak hearts without other evidence of disease; in the dyspeptic; in those subject to gout, especially if an attack is impending; and in those whose habits and occupations involve exhaustion of the nervous system.

Functional disorders of the heart are not infrequently associated with pain. This may be confined to the præcordia, especially the apex region or right border of sternum, but, like the pain of true angina pectoris, it often radiates over the left side or to the neck, axilla, and down the left arm. It may

be more or less paroxysmal, sharp, or cutting, or persistent, dull, and heavy. The pain is very frequently associated with flatulence, and is relieved in such cases by the remedies appropriate to this condition. Pain is not proportional to the intensity of the other symptoms. It may be absent altogether when palpitation is extreme, and may be persistent while other symptoms are in abeyance. In some rare cases, pain may be the indication of urgent, or even of fatal, disorder; this is evidenced by the well-known effects of a severe blow in the epigastrium, or of sudden mental shock. These are illustrations of purely functional angina pectoris; but for the most part this symptom has its origin in structural lesion of the heart itself. See *ANGINA PECTORIS*.

PHYSICAL SIGNS.—The physical signs referable to the cardiac action may be conveniently separated into the following groups, although in practice they will be found associated with each other: (1) *Increased or diminished impulse*; (2) *rhythmical disturbance*, with intermissions; (3) *increased or diminished frequency*, the rhythm and force being normal; (4) *haemic murmurs*.

1. An *increased impulse* may be the only evidence of disorder, or, more frequently, it may be complicated by some rhythmical disturbance.

On palpation the impulse is felt in two, three, or more interspaces, and to the untutored hand may suggest the existence of a true fremitus. On auscultation, the sounds are more difficult of appreciation than in simple palpitation; they are loud and clear, and sometimes so exaggerated and pronounced as to be audible both in the mammary and epigastric regions. When there is an unusual amount of irregular functional excitement in systole, there may be occasionally heard, as a passing, but not persistent occurrence, a reduplication of the second sound.

In cases where the *impulse is diminished*, the special characters are somewhat negative; the sounds being feeble, but otherwise normal, except in those cases in which some irregularity of action, or sharpness of the sounds, is present.

2. *Errors in rhythmical action* may be classified under the heads of irregularity and intermittence. The irregularity may be in the force or in the frequency of the beats. Every variety of irregular frequency may occur. Sometimes there appears to be a kind of order in rhythmical disorders—that is, short series of varying irregularities may regularly succeed each other. True intermittence is not so frequent as irregularity; but when intermittence does occur, it is generally associated with irregularity. These disturbances may be only momentary or of long duration, slight or considerable; but, however this may be, their character is determined by the irregularity in the recurrence of the systole, and the consequent prolongation or retardation of the period of intermission in the systole.

The physical examination reveals the nature of the irregularity. The sounds generally are intensified, the first sound being sometimes heightened to the extent of a sharp knock; while the second, save in intensity, is not materially altered.

Occasionally there is met with an appreciable rhythmical disturbance in the pulse, which is not found to exist in the heart—*false intermittence*. The heart only indicates irregularity of power; and as there is occasional failure of force in the already weak systolic contractions, the impulse is not communicated to the artery at the wrist. These false

intermissions accompanying irregularity most frequently occur when the heart is oppressed by flatus in the neighbouring viscera, or is excited by the injudicious use of tea or tobacco. The sensation communicated to the patient is that of a disagreeable flutter or 'tumbling over' of the heart.

Rhythmical irregularity occasionally appears as a normal condition, having a lifelong existence. Some cases are marked by an extension of the pause, with unsteadiness of the systolic impulse; others by its apparent extinction, so that there exists a rapidity of beats defying all analysis—tachycardia; but tachycardia also occurs either as an habitual state, or in paroxysms. See TACHYCARDIA.

3. Functional disorder occasionally assumes the form of either *increased or diminished frequency*, while the force and rhythm remain normal. Each of these conditions may be congenital and proper to the individual, or may be the result of abnormal influences. The functionally fast beat is generally induced by other diseases, as fever, diabetes, tuberculosis, &c., and is indicative of injury to normal innervation. The slow and drawing beat is generally met with where the nerve-power is healthy, but the heart itself is weak or fatty; or there is a perverted innervation under the influence of digitalis, aconite, or injury to the ganglionic system—a blow in the epigastrium offering a familiar example. See BRADYCARDIA.

4. *Inorganic murmurs* are frequently heard in functional disorders of the heart, but especially in those cases of hæmic disorder where the systolic impulse is increased, and there is rhythmical irregularity. These hæmic murmurs have the special characters usually attached to such sounds. They are systolic, basic, loudest in the second left intercostal space, and are not conducted in the course of the great vessels. There is, as a rule, no apex-murmur; but at the apex, synchronously with the basic murmur, the first sound is clearly defined, with a loud ringing second sound. The murmurs vary in character: sometimes they are hard and rough, sometimes soft and blowing. The seat is in the pulmonary artery, and, as a rule, they are accompanied with palpitation: this palpitation may be persistent, though the murmurs are not. The murmurs are generally associated with the venous hum to be heard in the jugular veins. Sometimes in hæmic cases a peculiar scratchy sound is present to the left of the sternum simulating pericardial friction, and giving rise to the erroneous diagnosis of pericarditis. See PERICARDIUM, Diseases of.

In other cases, functional murmurs are of exocardial origin, and to some of these the term *cardio-pulmonary* has been applied. Cardio-pulmonary murmurs are generally short, whiffing, systolic murmurs, audible only at or near the apex when the heart's action is excited. They are usually more marked at the end of inspiration when the lung is distended, and are weaker or disappear during expiration. They are probably due to the sudden compression of the lung by the forcible cardiac impulse. Their limited and localised position, their association with excited cardiac action, and their varying intensity with the phases of respiration are important points in their diagnosis. Apical systolic murmurs are also met with when the heart is displaced by pleural effusion, by pulmonary disease, or by thoracic deformities. The exact mode of production of these murmurs, which may be called *displacement murmurs*, is

uncertain. Systolic murmurs of peculiar cavernous quality may be audible over pulmonary cavities when these are in close anatomical relation with the heart.

COMPLICATIONS AND SEQUELÆ.—The several functional disorders of the heart are often complicated with other diseases—many external to the heart, and some of the heart itself. The more prominent of the former are disorders of the nervous system and of the blood. The diseases of the heart with which functional disorder may be complicated are mainly degenerations of the walls and valvular lesions. In all these cases the amount and urgency of the functional disturbance are no indication of the urgency of the disease with which it may be complicated.

DIAGNOSIS.—In order to make a correct diagnosis, the first consideration is to ascertain the entire absence of structural disease; or, should it be present, whether it be adequate to cause the full amount of the symptoms exhibited. If the heart have its normal position and dimensions, and if the sounds, though weak, be natural in tone and quality, it may be concluded that the cause is functional only, in the absence of any abnormal physical disease. The same may be said of rhythmical irregularities, except when arising for the first time in an old person. When the symptoms are associated with hæmic murmurs, the character of the murmur, its seat, and its persistency must be considered in connection with the absence or the presence of blood-disease. It must be always borne in mind that the absence of the physical signs of disease is not always conclusive of there being no structural lesion, for lesions do not always yield evidence of their existence. In doubtful cases, repeated examination will generally lead the experienced observer to a correct diagnosis.

PROGNOSIS.—The prognosis of functional disorders of the heart, for the most part, is favourable. Functional rhythmical irregularity, as a rule, does not indicate danger, but it may do so if associated with some obscure structural lesion. Nevertheless, cases of simple functional disorder, so severe as apparently to indicate an immediately fatal termination, prove, for the most part, manageable, and result in a restoration to health. The freedom of the heart from all agitation and other indications of disease, before and after an attack, is due to its being a normal and uninjured organ; and though liable during an attack to the morbid influences of spasms and congestive loading, it still may be a healthy organ. This holds whether the periods of disorder be short or prolonged, occurring rarely or frequently recurring. They are distressing but not dangerous. Irregular action may persist for years, and, in some cases, has lasted from early life to extreme old age.

TREATMENT.—The treatment of functional disorders of the heart should have reference primarily to the removal or cure of the exciting causes and, secondly, to the mitigation of the symptoms.

Treatment during the paroxysms.—In cases of simple palpitation the remedies which usually prove most successful are antispasmodics and carminatives. Among these may be mentioned sal volatile, spirit of ether, foetid spirit of ammonia, compound tincture of lavender, compound spirit of horse-radish, tincture of sumbul, and peppermint. Digitalis is recommended by many authorities for the relief not only of ordinary palpitation, but also of paroxysmal

tachycardia. In many cases of functional rapidity or irregularity it proves useless. Belladonna will sometimes relieve when digitalis fails, especially in cases of rapid and intermittent cardiac action. It may either be used internally in ten-minim doses of the tincture, or applied externally to the præcordial region in the form of plaster, or liniment sprinkled on impermeable piline. In cases where sleeplessness and distress accompany the rapid action, opium sometimes proves more useful than any other remedy; but it is a drug which must be used with caution. Where there are signs of failing heart, strychnine and caffeine may be given either by the mouth or hypodermically. In cases where the functional disorder arises from indiscretions in food and drink, a dose of calomel or blue-pill followed by a saline aperient is indicated. It is hardly necessary to say that in the more severe cases the patient must be kept in bed at rest in the horizontal position. Alcohol, although useful in exceptional cases, is a dangerous remedy. If it relieves, the patient is apt to fly to it on the appearance of the slightest signs of heart-disorder; and we have met with cases where the effects of alcoholism had become far more serious than the original disorder for which the stimulant had been prescribed.

Treatment between the paroxysms.—The paroxysm being allayed, it is then well to correct any disordered condition which may probably have been its exciting cause. Dyspepsia is to be relieved, the liver is to be set right, the uterine functions are to be restored to regularity, loaded bowels emptied, plethora subdued, anemia cured, exhaustion compensated for, and debility counteracted. The overworked must seek renovation in travel and cheerful recreation. In persons prone to these disorders many precautions should be observed. The food should be moderate in quantity and unstimulating in quality; tea, coffee, alcohol, and tobacco should be eschewed; and exercise should be unfatiguing, and chiefly taken in the open air. Hot, crowded, and ill-ventilated rooms, and the postponement of sleep by late hours, should be especially avoided. A careful mental discipline should be observed; and this must be sought in a healthy exercise of the brain. As all the varieties of functional disorder of the heart are peculiarly under the influence of a morbid will, it is important that the medical attendant should generally encourage and cheer; and as soon as careful investigation has satisfied the requirements of a just prognosis, further investigations by the stethoscope should be avoided.

THOMAS SHAPTEL.

HECTOR MACKENZIE.

HEART, Granular Degeneration of.—

SYNON.: Parenchymatous Degeneration; Cloudy Swelling.

ÆTIOLOGY AND MORBID ANATOMY.—See DEGENERATION.

SYMPTOMS.—Inasmuch as parenchymatous degeneration of the heart is usually but a complication of some acute specific disease, the condition of the patient is one of great febrile prostration with cardiac asthenia. The physical signs, which are regarded as more distinct evidence than the symptoms of the condition of the heart, include feebleness, advancing to complete absence, of the apical impulse, or more rarely palpitation; and progressive weakening, and finally loss, of the first sound. The pulse corresponds with the feeble condition of

the heart; indeed, in some cases it is imperceptible although associated with cardiac palpitation.

PROGNOSIS.—The existence of granular degeneration of the heart adds seriously to the gravity of a case of fever. The danger increases with the rate and weakness of the pulse, and with the feebleness of the cardiac impulse and first sound. The re-appearance of the first sound under observation justifies a favourable prognosis.

TREATMENT.—The existence of this condition is to be regarded as an important indication for the use of alcoholic and other cardiac stimulants.

J. MITCHELL BRUCE.

HEART, Hæmorrhage into the Walls of.—

SYNON.: Cardiac Apoplexy.

ÆTIOLOGY AND PATHOLOGY.—Rupture of the heart is the most frequent origin of hæmorrhage into the walls of the organ. The blood in these cases may be derived either from the cavity of the ventricle, or, more rarely, from a coronary vessel ('cardiac apoplexy'). In both classes fatty degeneration of the muscular fibres is generally present. The coronary arteries are also a source of hæmorrhage in rupture of a coronary aneurysm, in ulceration of their walls, and in embolism or thrombosis leading to infarction. The formation of acute aneurysm of the heart is necessarily attended by hæmorrhage (see HEART, Aneurysm of). Ecchymoses in the walls of the heart are met with in granular degeneration of the heart; in fatty degeneration due to poisoning by phosphorus or arsenic, in the so-called 'hæmorrhagic' diseases, such as purpura and scurvy, and especially in cardiac and pulmonary disease.

In non-fatal hæmorrhage into the walls of the heart, the blood undergoes the changes usual in extravasations, and gives rise to collections of pigment-particles between the muscular fibres, to blood-cysts, or to collections of puriform matter. See EXTRAVASATION.

Hæmorrhage into the myocardium possesses no special clinical relations.

J. MITCHELL BRUCE.

HEART, Hydatid disease of.—This is a rare disease; yet, according to Cobbold, 3·5 per cent. of all cases of hydatids in man occur in the heart.

ANATOMICAL CHARACTERS.—Hydatid cysts of the heart are either simple or multiple, the latter being the more common. They are situated in the myocardium of either side of the heart, and project into the pericardial sac or one of the cavities in the form of a cyst. In other cases the parasite undergoes degeneration and remains quiescent, its existence being unsuspected. Hydatids may rupture or be dislodged from their seat in the cardiac wall—either inwards or outwards or in both directions at once. In the first event, the parasite or its contents or fragments become impacted in the cardiac cavities or orifices, or give rise to embolism of the great vessels or of a distant artery. Rupture into the pericardial sac causes pericarditis; rupture both internally and externally has given rise to hæmato-pericardium.

Hydatids of the heart are frequently associated with the same disease in other viscera. See ENTOZOA.

SYMPTOMS.—In several cases of this disease, the subjects have died suddenly. These persons were not known to have suffered previously from sym-

ptoms referable to the heart. In other instances the ordinary phenomena of chronic cardiac disease were present, including endocardial murmurs; but it is not certain that these were in every case due to the presence of the hydatids in the heart. A sudden fatal termination will result from internal rupture and embolism, or from hæmato-pericardium. The disease does not appear ever to have been suspected during life. Cardiac symptoms and signs, or sudden death, occurring in an individual known to be suffering from hydatids of other viscera, would suggest that the heart was possibly also affected.

The disease cannot be said to have any special interest therapeutically.

J. MITCHELL BRUCE.

HEART, Hypertrophy of.—SYNON.: Fr. *Hypertrophie du Cœur*; Ger. *Hypertrophie des Herzens*.

DEFINITION.—An excessive uniform growth of the tissues of which the heart is composed, the result of which is an abnormal increase in the weight and bulk of the organ.

ANATOMICAL CHARACTERS.—The most important anatomical change in cardiac hypertrophy is an increase of the proper muscular tissue of the heart. There may be hypertrophy of only one part of the cardiac walls, abnormal thinning being found in other parts. The organ may be greatly enlarged from general dilatation, without any notable thickening of the walls; but the capacity of the chambers, and especially the gross weight of the organ, should always be carefully noted in estimating the degree of hypertrophy, as there may be a greatly augmented extent of wall, although its actual thickness seems normal. Simple hypertrophy is very frequently the first condition, preceding hypertrophy with dilatation. See HEART, Dilatation of.

The increase of weight and bulk may be due to (1) augmentation of the size of the muscular fibrillæ, which may become more than double that of the normal; (2) the formation of new muscular fibres; (3) increased development of blood-vessels; (4) augmentation of connective tissue; and (5) fatty accumulation. In the course of time the hypertrophied tissue may unduly press upon the blood-vessels and contribute to induce degeneration, while the continuance or increase of the primary cause of obstruction may lead to dilatation of the cavity (auricle or ventricle), the work of which is obstructed.

GENERAL CONSIDERATIONS.—The weight of the heart of the infant at birth becomes more than doubled at the age of two years. Between seven and fourteen years of age it is about eight times the weight at birth; from fourteen to twenty the increase is such that the weight is again nearly doubled. There is, speaking generally, progressive augmentation even to old age, due more to the augmentation in the weight of the great vessels within the pericardium than to that of the heart-substance itself.

The average weight of the female being less than that of the male, the heart of the former is of course less. It will be readily seen that, as the weight of the heart varies with that of the individual, one cannot express with exactitude any figure as the normal weight. We may roughly say that the heart of the adult should weigh about 10 oz. One that weighs 12 oz. is hypertrophied. The weight of an hypertrophied heart may vary between this and the

enormous figure of 60 oz., which has been recorded; not uncommonly it reaches 27 to 30 oz.

VARIETIES OF HYPERTROPHY.—Bertin in 1811 described three forms, which most succeeding writers have referred to, namely: (1) *simple hypertrophy*, in which the parietes of the compartments are thickened, the cavities retaining their natural dimensions; (2) *hypertrophy with dilatation* (*eccentric hypertrophy*), in which the cavities are increased in capacity, while the parietes are either of natural or of augmented thickness; (3) the so-called *concentric hypertrophy*, or *hypertrophy with diminished cavities*, in which new material was supposed to be added, chiefly in the interior of the ventricular walls. It is, however, now generally agreed that *concentric hypertrophy* of the ventricles has no real existence. The appearances which have given origin to the term are due, in the great majority of instances, to the occurrence of *rigor mortis* in the muscle of the ventricle, which has caused firm contraction, and thus diminution, to almost obliteration, of the cavity. If a heart presenting such signs be soaked for some hours in warm water a gentle dilatation with the finger will restore the ventricle to its normal dimensions. The left ventricle may simulate concentric hypertrophy in some cases of mitral stenosis when the disease has developed in early childhood. The ventricle has not received its normal blood-contents, and development has proceeded disproportionately in the right chambers and the left auricle. The cavity of the left ventricle has thus been left relatively small till the time of death. In like manner, in congenital stenosis of the pulmonary artery the *right* ventricle, hypertrophied in intra-uterine life, may so continue, and its cavity never become dilated to the normal extent. The ventricles are much more frequently hypertrophied than the auricles, and the left ventricle more frequently than the right.

I. Hypertrophy of the left ventricle.—**ANATOMICAL CHARACTERS.**—The whole heart appears to be elongated, and the apex-portion of the left ventricle especially prolonged. The walls of the left ventricle and the inter-ventricular septum are thicker and firmer than in the normal; the septum may bulge into the right ventricle, diminishing its capacity and even producing actual obstruction of its *conus* (Coats). In transverse section the thickening and bulging of the septum are very manifest, the right ventricular cavity presenting the appearance of a crescentic appendage to the left chamber.

ÆTIOLOGY AND PATHOLOGY.—Hypertrophy of the left ventricle occurs under many different conditions.

1. Quain attached considerable importance to such *nervous* causes as prolonged mental excitement or strain, and those emotional conditions which produce frequent palpitation (see HEART, Functional Disorders of). It is, however, only in a small proportion of cases that a heart which beats for long periods at an abnormal rate of rapidity becomes hypertrophied. The correct view seems to be that for the production of hypertrophy of the left ventricle in cases of nervous excitation there must be an additional factor besides rapidity—either a thickening of the arteries, or a vaso-motor irritation causing contraction of their muscular walls, whereby the intra-arterial tension is increased. If the blood-pressure be at or below the normal, the rapidly beating heart does not tend to hypertrophy.

2. Among *mechanical* or *physical* causes are all those obstructive conditions to be specially examined

presently. Violent and long-continued athletic or other exercises, which notably accelerate the contractions of the heart, or produce excessive blood-pressure, may be mentioned here. It has been pointed out that great muscular exertion with the arms is specially prone to cause hypertrophy, as in the case of hammer-men. Prolonged working in a bent or constrained position is also mentioned as a cause.

In some callings and conditions in which muscular effort is severe, hypertrophy of the left ventricle is prone to occur—e.g. dwellers in hilly regions, especially those accustomed to carry heavy loads (Münzinger, Allbutt), stonemasons, slaughterers (Leyden). In many cases it is probable that the two factors just mentioned—nervous excitation and muscular overstrain—combine to produce the hypertrophy. So may be best explained the signs and symptoms in the cases of ‘irritable heart’ of soldiers during the American Civil War (Da Costa), those in our own Foot Guards who carried heavy accoutrements (Myers), and those in the Franco-German war (Fraentzel) (*see EXERCISE*). The excitement of a soldier’s life co-operates as a cause with the muscular effort which may be excessive and either prolonged or violent and fitful. It is a significant observation of Hirsch that there has been a notable increase in the proportion of heart-diseases in a community at times of great political and social excitement.

3. *Diseases of the valvular apparatus*—aortic and mitral—induce hypertrophy of the left ventricle by causing an obstruction to the outflow of blood, or an abnormal blood-pressure within the cavity from regurgitation. (a) *Stenosis of the aortic orifice* is a common cause of hypertrophy of the left ventricle. The opening is not only narrowed, but is also rendered more rigid, and thus increased force is necessary to propel the blood. Along with the valvular lesion there may also be, especially in advanced life, a loss of elasticity and a roughening of the inner coat of the aorta from degenerative changes—conditions which increase the mechanical strain upon the left ventricle. (b) *Aortic regurgitation* often induces so great enlargement of the left ventricle, from hypertrophy and dilatation, that the heart in such cases merits the name *cor bovinum*. The back-flow of blood increases the intra-ventricular pressure, tends to dilate the cavity, and calls forth augmented efforts of ventricular contraction. In some cases of injury and rupture of the aortic valves it has been possible approximately to estimate the rate of hypertrophy. In two cases, related by Stone, of injury to these valves by blows upon the chest, assuming that the heart was healthy previous to the injury, there must have been an increase in weight of nearly an ounce a week during the four or five weeks that elapsed before death. (c) *Mitral regurgitation*. Insufficiency of the valve at the left auriculo-ventricular orifice of necessity causes the left ventricle to be subject to abnormal pressure, with the result that it becomes hypertrophied as well as dilated. In pure *Mitral Stenosis*, on the other hand, the left ventricle is of normal dimensions or is smaller than the normal. If the left ventricle at any *post-mortem* examination in cases of this disease be seen to be hypertrophied, there is some superadded cause for such hypertrophy—e.g. arteriosclerosis, or pericardial adhesions.

4. *Aneurysm of the aorta*.—There has been much difference of opinion on the question whether aneurysm of the thoracic aorta is a cause of hyper-

trophy of the left ventricle. The divergence is capable of explanation. When the situation of the aneurysm is at the commencement of the aorta, where it involves the semilunar valves, hypertrophy is the rule. When the aneurysm is so situated as not to involve the valves, hypertrophy is a rare exception. This is proved to demonstration by the following figures, deduced from the records of the London Hospital. Of forty-one cases of aneurysm of the thoracic aorta in which the valves were *not* implicated, enlargement of the left ventricle was evidenced in only nine instances, and in three of these the hypertrophy was recorded as only slight. In forty-one cases in which the valves were *involved*, hypertrophy and dilatation were manifested in thirty-five. The writer has seen *post mortem* many cases in which, though a huge aneurysmal sac was observed on the thoracic aorta well above the valves, the heart was small.

5. *Renal disease*.—Hypertrophy of the left ventricle may occur in several forms of renal disease. Of these the ‘granular contracted kidney’ is a very important cause, the hypertrophy being often of the purest type, without dilatation. This change is the result of the great increase of blood-tension produced by the resistance offered to the blood in the small arteries—probably also in the capillaries—throughout the whole body, as well as in the kidneys.

6. *Pregnancy*.—It has been shown by many observers that the left ventricle tends to become hypertrophied and the arterial tension augmented during pregnancy. The hypertrophy may continue for a considerable portion of the period of suckling, and then the heart, like the uterus, may undergo a process of involution. According to Duroziez, the ventricle tends, after many pregnancies, to remain hypertrophied.

PHYSICAL SIGNS OF HYPERTROPHY OF THE LEFT VENTRICLE.—In simple hypertrophy (e.g. when occurring in athletic persons, or in relation with chronic renal disease in the earlier periods) the wall of the chest on *inspection* may be observed in the neighbourhood of the apex to be raised with each ventricular systole. Pulsation, also, of the carotid arteries in the neck may be observed, such pulsation being rather prolonged, and not sudden (as in aortic regurgitation), unless there be concurrent fever. On *palpation* the fingers are lifted by the apex, the impulse of which is prolonged and heaving. The duration of the heaving impulse is in proportion to the degree of hypertrophy. The impulse is often strong enough to move the bed-clothes visibly, and even to raise the head of the auscultator by the impact against the stethoscope. Of course a larger portion than usual of the heart’s surface impinges against the chest-wall. The outline of the apex-portion of the heart, as obtained by *percussion*, is acutely triangular, its acute angle pointing downwards and to the left. This becomes broader and more rounded as dilatation preponderates over hypertrophy. In simple hypertrophy the heaving apex may be in the sixth or seventh, rarely in the eighth, left intercostal space; but in dilatation with hypertrophy the area downwards and towards the left axilla is greatly increased. On *auscultation* the first sound at the apex is found to be dull and prolonged. It is the sound of muscular contraction that the ear in the greatest degree appreciates, the element of valve-tension being muffled by the thick wall of the ventricle. Over

the second right costal cartilage the second sound is loud, and may have a ringing character; it may sometimes be the only one of the two normal sounds audible. In this situation it is much louder than over the second left interspace (the commencement of the pulmonary artery) unless the ventricular hypertrophy is accompanied by mitral insufficiency. If, with evidence of powerful left ventricle and firm arteries, the aortic second sound is not loud, but dull and ill-pronounced, there is strong probability that the aortic cusps are swollen or thickened from disease. In later stages of hypertrophy, when the muscular tone of the left ventricle is impaired, the sounds of the heart may have a triple rhythm, resembling the cantering of a horse—the *bruit de galop*. This is especially observed in the hypertrophy associated with renal disease, and in the hypertrophy with dilatation accompanying gastro-hepatic derangement.

The *radial pulse* is felt to be prolonged; the artery is firm and resisting, and its coats may be thickened. In the hypertrophy resulting from muscular overstrain the pulse is large and full, the first wave is prolonged, and there is no diastolic. In chronic renal disease, as the arterial coats become thickened the amplitude of the pulse is manifested in less degree, the vessel being felt hard, resisting, and full between the beats. In some cases the fullest force exerted by the finger may fail to obliterate the pulse entirely, and on the distal side of the point compressed the wall of the artery may be felt cylindrical and firm. In the hypertrophy associated with aortic stenosis the pulse is somewhat small and gradual both in its rise and fall. In that manifested with aortic incompetency it is sudden and powerful in its impact against the finger, but rapidly receding, so that the artery seems empty between the beats—it is the collapsing or 'water-hammer' pulse.

SYMPTOMS OF CARDIAC HYPERTROPHY.—It must not be forgotten that simple hypertrophy may exist without producing symptoms which attract the attention of the patient, and that there is a natural tendency to some degree of cardiac hypertrophy with the advance of age. *Dyspnœa*.—In moderate hypertrophy without complication, there is usually easy and natural breathing when the patient's body and mind are at rest. But mental excitement or bodily effort at once induces more or less of temporary dyspnœa. In some cases the due expansion of the lungs may be mechanically impeded by the increased volume of the heart. In eccentric hypertrophy with dilatation, more especially when the right cavities are thus affected, pulmonary congestion and œdema are usually present, and then marked dyspnœa is a prominent and distressing symptom. *Cough*.—In simple hypertrophy there may be an occasional dry, irritating cough, and in young plethoric women a wheezing cough may be complained of. In right-side enlargements, when pulmonary obstruction and dropsical effusions supervene, cough is, in most cases, a very frequent and painful addition to the other sources of discomfort to the patient. *Hæmoptysis and other hæmorrhages*.—Hæmoptysis from capillary engorgement is common, being generally active and sudden. In hypertrophy of the left ventricle there is often active distension, and sometimes rupture, of the branches of the bronchial arteries. The cerebral arteries are also specially liable to give way. Epistaxis may also be due to cardiac enlargement. *Palpitation* is a

common symptom in all organic diseases of the heart, and is often very marked in cardiac enlargements. The least excitement, bodily or mental, may induce a greater or less degree of this symptom. Especially in hypertrophy with dilatation, most distressing paroxysms of palpitation are apt to occur from time to time. Besides bodily and mental excitement, other conditions, such as indigestion, flatulence, or an overloaded stomach, readily call forth this symptom. When there is much dilatation, the palpitation may be irregular and intermittent, and is then more particularly a very alarming symptom. It must be remembered, however, that palpitation of the heart often occurs in the absence of any structural heart-disease.

The *renal and urinary* derangements are very important. In the hypertrophy of the left ventricle, associated with chronic Bright's disease, there will be found the copious excretion of a pale urine of low specific gravity. Albumen may be found in small quantity, and may sometimes be absent. In the hypertrophy associated with gastro-hepatic disturbance, the urine will be scanty, of high specific gravity, often thick with urates, containing much urea, and dark with the colouring-matter of the urine, of the bile, or of both.

Certain *cerebral symptoms* ought to be mentioned in connection with the other more direct signs of cardiac hypertrophy. A feeling of fullness, or perhaps of throbbing, may be felt in the head after great muscular exertion or mental excitement. In many cases there may be headache, ringing in the ears, vertigo, *muscæ volitantes*, and disturbing dreams.

II. Hypertrophy of the right ventricle.—

The capacity of the right ventricle is generally greater than that of the left—according to recent researches in the proportions of about seven to six. The walls are from one third to one half the thickness of those of the left.

In the great majority of cases the right ventricle becomes hypertrophied only in association with a morbid change in the left, and when such hypertrophy occurs it is nearly always accompanied by dilatation.

The right ventricular wall may be thickened to the extent of half an inch or even an inch, instead of the normal eighth of an inch; its greatest thickness is at its base. Thus the wall of the hypertrophied right ventricle may be as thick as that of the normal left ventricle. The columnæ carneæ of the right ventricle are even more liable to hypertrophy than the wall. In dilatation with hypertrophy the columnæ carneæ become stretched and attenuated. The substance of the hypertrophied left ventricle can generally be torn with ease, while that of the hypertrophied right ventricle is usually tough and leathery.

ÆTIOLOGY AND PATHOLOGY.—The right ventricle may be observed in a state of simple hypertrophy in—

1. *Congenital anomalies of the heart*.—Chief of these is stenosis of the pulmonary artery, which in the majority of cases results from foetal endocarditis. The obstruction may be below the valves, the conus of the right ventricle being narrowed. In each case the right ventricle becomes hypertrophied in consequence of the obstruction in front, and there is no dilatation of the cavity. See HEART, Malformations of.

2. In *emphysema, fibrosis, and consolidated or*

compressed conditions of the lungs, the impediment to the pulmonary circulation induces hypertrophy with dilatation of the right ventricle.

3. In the subjects of *curvature of the spine* the capacity of the thorax is nearly always diminished; the lungs are emphysematous, and often suffer other pathological changes. The two branches of the pulmonary artery may be unequal, owing to the differences of development of the two lungs. The right ventricle is dilated as well as hypertrophied.

4. *Endocarditis affecting the tricuspid valve*.—It is rarely that endocarditis attacks the valvular apparatus of the right side of the heart without that of the left side participating in still greater degree, except in intra-uterine life. In some cases (and these not very infrequent) the result of endocarditis is stenosis of the tricuspid orifice, in which case the right ventricle tends to hypertrophy, probably on account of the co-existing mitral stenosis, while the right auricle becomes greatly dilated.

5. The most common cause of hypertrophy with dilatation of the right ventricle is *valvular disease of the left side of the heart*. Whether there be mitral stenosis or regurgitation, the consequences are hypertrophy of the right ventricle and dilatation on account of the persistent overstrain.

SIGNS AND SYMPTOMS OF HYPERTROPHY OF THE RIGHT VENTRICLE.—In enlargements of this ventricle, *inspection* may reveal a rounded smoothness of the epigastrium, with perhaps some bulging of the ensiform and lower left costal cartilages. The præcordial impulse may be seen to be very diffused, extending towards the tip of the ensiform cartilage. Facial lividity is frequently seen; and jugular pulsation may be observed when there is tricuspid regurgitation. *Palpation* over the lower part of the sternum detects an impulse, which feels as if immediately under the hand, and usually lacks the heaving character of the impulse of an hypertrophied left ventricle. Epigastric pulsation is often very pronounced. The liver-pulsation in such cases may result either from venous regurgitation or from right systolic action exerted through the diaphragm. On *percussion*, the inferior line of dulness is found to extend lower down and farther towards the right than normal, sometimes reaching an inch or more beyond the right sternal edge. On *auscultation*, the second sound over the pulmonary valves is found to be louder than over the aortic. The accentuation of the pulmonary second sound, however, is not so marked as in cases of well-compensated stenosis or insufficiency at the mitral orifice. The aortic second sound is weak, and though palpation may detect a forcible impulse at the apex of the heart, the radial pulse may be felt small and contracted. In some cases a triple sound—the *bruit de galop*—may be heard over the right ventricle.

The *radial pulse* in hypertrophy of the right ventricle is usually small and resistant. There is a difficulty in the passage of blood through the pulmonary circuit, and the supply to the left chambers is reduced in amount; moreover, the blood is imperfectly oxygenated and, containing an undue proportion of carbon dioxide, it stimulates the vaso-motor centre and augments the intra-arterial tension.

III. Hypertrophy of both ventricles.—**COMPLICATIONS AND SEQUELÆ.**—Simple hypertrophy of the heart may go on quietly for a long time, just balancing the obstructive influence, and

giving rise to no other form of disease. But when dilatation co-exists with hypertrophy, palpitation, dyspnoea, venous congestion, and serous effusions are the ordinary results. Diseased conditions of the arteries may occur simultaneously, or may be induced by the long-continued additional strain put upon them by an hypertrophied heart. Cerebral hæmorrhage often occurs in connection with an hypertrophied left ventricle, as in Bright's disease; although there are always perhaps other factors, besides the mere excessive propulsive power of the heart, in the production of apoplexy. Pulmonary and general congestion and oedema are the usual attendants of mitral lesions with right-side enlargements. Pulmonary hæmorrhagic infarction (the so-called 'pulmonary apoplexy') generally results from greatly lowered pressure, due to plugging or other cause, in some branch of the pulmonary artery, and takes place in connection with right-heart enlargement. Sanguineous exudation in the tract of the bronchial mucous membrane may occur in left-heart hypertrophy. Persons suffering from cardiac hypertrophy are apt to be gravely affected by acute febrile diseases, because the resultant acceleration of the heart's action increases the embarrassment of the organ. Hypertrophied cardiac walls are peculiarly liable to the fatty degenerative changes described elsewhere. See HEART, Fatty Degeneration of.

IV. Hypertrophy of the auricles.—Hypertrophy of the *right* auricle is scarcely ever met with except in association with dilatation of the cavity. Simple hypertrophy is only possible in the case of tricuspid stenosis occurring in infant life. Hypertrophy and dilatation are marked in cases of mitral disease, both regurgitant and obstructive. The hypertrophy is in greater degree in the obstructive lesion. In both, but especially the latter, the auricle may be sufficiently powerful to cause a back-flow into the venous channels by its systole, and thus a venous pulsation, presystolic in time, in the veins of the neck. Hypertrophy of the *left* auricle occurs in greatest degree in mitral stenosis. The writer found, in a boy of nine, a left auricle varying in thickness from one eighth to one quarter of an inch—i.e. the thickness in some parts being nearly that of the right ventricle of an adult. In some cases—in children—the hypertrophied auricle may be observed to cause a distinct presystolic pulsation in the third left intercostal space at the outer portion of the cardiac dulness. It has been considered by many observers that the earliest and most characteristic change in the left auricle in mitral stenosis is dilatation. Samway, from a review of the *post-mortem* records of 70 cases at Guy's Hospital, found that in pronounced mitral stenosis the characteristic modification of the left auricle is not dilatation but hypertrophy. In the later stages of the disease dilatation occurs, and the muscular wall becomes thin. An increase of dulness to the left over the situation of the left auricle is often manifested on percussion in cases of mitral stenosis.

V. Hypertrophy of the whole heart.—This is manifested in the highest degree in cases of combined aortic and mitral disease; either when a rheumatic lesion has induced mitral and aortic regurgitation coincidentally, or when the initial lesion has been aortic regurgitation, and mitral inadequacy has resulted from the abnormal intra-ventricular pressure. In mitral disease, however, when the aortic valves are intact, the hypertrophy and dilatation of both ventricles may be very considerable.

Differences of opinion have been expressed as to the influence of *pericardial adhesions* in determining hypertrophy of the heart. Pericarditis is a potent cause of rapid hypertrophy during the period of childhood. A heart presenting signs of almost universal pericardial adhesion will be often found to evidence a far greater degree of hypertrophy than could be ascribed to any co-existing valvular imperfection. When the period of heart-growth has ceased, in fully adult life, the enlargement is less marked.

PATHOLOGY.—True muscular hypertrophy of the heart is compensatory or conservative. The heart obeys the law that muscle tends to increase in force and in development when an obstacle is imposed to its normal working (*see* HYPERTROPHY; and HEART, Valves and Orifices of, Diseases of). We have just seen what the obstacles are in hypertrophy of the different parts of the heart. Some obstacles are direct, such as stenoses; and by hypertrophy the heart is enabled to overcome deficient valvular action or obstruction to the blood-current, the increased peripheral resistance of Bright's disease and of emphysema. Other lesions are indirect or relative obstacles, particularly valvular incompetence, which permits over-filling of the cavities, and demands a corresponding increase of vigour in the systolic discharge, which leads to hypertrophy.

DIAGNOSIS.—An extended area of dullness, displacement of the apex-beat downwards and to the left, and a comparatively slow, heaving systolic action, with augmented force of impulse, are the chief diagnostic physical signs of cardiac hypertrophy. In *young and thin people* the last of these signs may seem to be present, but the accompanying conditions readily exclude hypertrophy, especially the non-extension of the cardiac dullness. An *emphysematous left lung* may mask hypertrophy; and contraction of the lung might suggest its presence to a superficial observer. In *pericardial effusion* the triangular shape of the area of dullness, with the apex of the triangle upwards, is a distinctive feature; there might also be the history of an acute disease, with lancing pain, dyspnoea or suffocative sensations, and other symptoms not found in mere enlargement of the heart. *Pleuritic effusion* or *aneurysm* would be still more readily discriminated. The differential diagnosis between left-heart and right-heart enlargements has been sufficiently discussed in speaking of the symptoms and signs. *Dilatation*, as distinguished from hypertrophy, is characterised by the feebleness and diffuseness of the præcordial impulse, which may even be quite imperceptible; and by the general signs and symptoms of a feeble circulation.

PROGNOSIS.—Simple, uncomplicated hypertrophy, as in the young and in athletes, is not incompatible with long life, if the cause be removed in time. According to the extent and degree of complication, whether in the form of valvular lesions or co-existent pulmonary disease, the prognosis will be unfavourable. When the cardiac change is itself producing secondary lesions, as degeneration of the arterial coats, when dilatation is advancing, and when there is Bright's disease, the prognosis becomes very unfavourable.

TREATMENT.—Hypertrophy being in itself a conservative change, protective from worse results, the primary object is to remove, if possible, the cause of the hypertrophy. To aim merely at reducing the hypertrophy, irrespectively of its cause,

as by lowering the nutrition, would favour the more serious evil of dilatation. All mental and bodily exertion which excites the circulation must be scrupulously avoided. Alcoholic stimulants should be taken sparingly, and no more wine allowed than such as may seem to benefit digestion. The diet should be carefully selected, nitrogenous food being generally necessary, though great care must be exercised to avoid excess in this direction. The digestive organs must be sedulously looked after, not only because good nutrition is very important, but also because flatulence and dyspepsia directly embarrass the heart's action. Mild saline and aloetic aperients with alteratives should be given. Diuretics will be necessary if there is a tendency to dropsy, and in all cases great attention must be paid to the removal of congestion when it affects important organs, and the restoration of their functions when affected, more especially of the liver and the kidneys. When there is great excess of cardiac action, direct cardiac sedatives, as aconite, diluted hydrocyanic acid, conium, and perhaps the local application of ice, may be called for. When there is dilatation or feebleness of the muscular substance along with the hypertrophy, iron and digitalis are the chief remedial drugs. A. E. SANSOM.

HEART, Inflammation of Lining Membrane of.—**SYNON.**: Endocarditis; Fr. *Endocardite*; Ger. *Endocarditis*.

Three forms of endocarditis are commonly described: (1) Simple endocarditis; (2) Ulcerative, or malignant, endocarditis; and (3) Chronic endocarditis. Only the first two will be discussed here. Chronic endocarditis is referred to under the head of HEART, Valves and Orifices of, Diseases of, p. 663.

Simple Endocarditis.—**ÆTIOLOGY.**—Endocarditis generally occurs in association with acute rheumatism and chorea; less frequently with other acute specific febrile diseases, such as scarlet fever, pyæmia, and septicæmia—including puerperal fever; more rarely with typhoid fever, variola, measles, and tonsillitis. It may be observed in the course of pregnancy, and after parturition, in acute and chronic Bright's disease, and in syphilis. Injuries of the heart, such as strain or rupture of the valves, may also lead to it; and local endocarditis is frequently the result of friction of one part of the endocardium on another during the cardiac revolution, as, for example, by growths from the walls or valves.

The cause of endocarditis is an irritant circulating in the blood. In many cases this is known to be an organism; in others it is probably a toxin or some other chemical irritant. See p. 652.

Age is an important predisposing factor in the ætiology of acute endocarditis, the occurrence of which as a complication of acute rheumatism is certainly most frequent in young subjects, and declines as age advances. Women are more subject to rheumatic endocarditis than men.

The localisation of the endocardial inflammation appears to be determined chiefly by pressure and tension, rather than by any peculiarity of the membrane itself, or of the blood in contact with it. Thus the left ventricle is almost the sole seat of the disease in the adult, and the right ventricle in the fœtus; while endocarditis is rarely seen beyond the boundaries of the valves, that is, the parts most subjected to strain. In the same way, chronic endo-

carditis is usually due to increased pressure within the heart, as in chronic Bright's disease, and in conditions that entail prolonged severe strain upon the valves during exertion. A similar cause is at work in pregnancy.

ANATOMICAL CHARACTERS.—Inflammation of the endocardium affects chiefly the valves and the chordæ tendinæ, and especially the lines of contact or the surfaces of the valves exposed to the force of the blood-current. The lines or points of contact of the valves present smooth, soft, warty projections, known as 'vegetations,' due to the formation of smooth thrombi upon small, necrosed, and generally swollen, areas of the endocardium. As the process advances, the affected areas become more opaque and firm, as well as larger. When the endocarditis has gone thus far, resolution is probably rare. The most common result is what is known as 'chronic valvular disease.' The affected parts are left opaque, puckered, and thickened by growth of connective tissue. As a consequence of these changes, the valves may become much altered in size and shape, and the ostia contracted and irregular, so that the mutual adaptation of the parts is greatly disturbed. Other results of endocarditis are not uncommon, such as adhesions between the neighbouring structures, and ossification or calcification of the new connective tissue. Laceration of the valves, rupture of the chordæ tendinæ, ulceration, suppuration, the detachment of vegetations, and the formation of aneurysm are rare events in this variety of the disease.

Microscopically, the formation of laminated thrombi is the most prominent change. These are formed on small areas of endocardium believed to have undergone necrosis, as their nuclei fail to stain. In some cases slight exudation may lead to swelling of the endocardium, and to the appearance of polymorphonuclear leucocytes at the margin of the affected areas.

The ultimate effects of these changes upon the functions of the valves and their appendages are described in the article **HEART, Valves and Orifices of, Diseases of.**

SYMPTOMS.—The symptoms of endocarditis are inseparable from the symptoms of the disease with which it is associated, and the diagnosis of it is made almost entirely from the presence of physical signs. Thus fever probably precedes the advent of endocarditis in every case; and it cannot be said that the simple uncomplicated disease in any respect affects either the pyrexia or any other element of the same. Local symptoms are almost equally rare, unless the endocarditis leads to serious lesion of the cardiac valves. As long as these remain sound, and the disease is acute and does not involve deeper structures, pain in the heart, præcordial distress, syncope, shortness of breath, and other symptoms of heart-disease cannot be said to occur at all frequently in endocarditis. The cardiac contractions are necessarily increased in frequency; and palpitation and dyspnoea may occur on movement. It is otherwise when the inflammation has lasted so long as to render the valves incompetent, or to obstruct the orifices; or when the myocardium is attacked and dilatation ensues. The symptoms just enumerated then make their appearance. In children, rheumatic endocarditis is peculiarly latent, while dangerously progressive or recurrent. See **RHEUMATISM, ACUTE.**

Physical Signs.—The physical signs of acute endocarditis are—increased extent and frequency, with

variable strength, of the visible and palpable impulse; moderate increase in the area of præcordial dullness, and various alterations in the cardiac sounds. At the beginning of endocarditis, the first sound at the (left) apex is frequently heard prolonged and hollow or muffled; and, as the process advances, this alteration of character may gradually pass into a murmur, which is at first indistinct but afterwards well-formed. If the aortic valves are affected, the second sound may similarly lose its characters, become dull, and finally be converted into, or be complicated with, a murmur. The most frequent murmur in acute endocarditis is mitral systolic; aortic murmurs are decidedly less common; and mitral præ systolic murmur is very rare. Various murmurs, inorganic or organic, may also appear and disappear during the course of the disease.

COMPLICATIONS.—Endocarditis is itself always a complication of the diseases previously mentioned. Myocarditis and pericarditis may be correctly regarded as complications of endocarditis when the inflammation begins in the lining membrane of the heart. According to some authorities, clots may form in the heart in endocarditis, and give rise to very urgent symptoms (see **HEART, Thrombosis of**). Embolism may arise from detachment of fragments of coagula or vegetations. Congestion or inflammation of the lungs and pleuræ frequently occurs in association with endocarditis, and so may albuminuria.

COURSE, TERMINATIONS AND SEQUELÆ.—The course of simple endocarditis varies with the course of the original disease with which it is associated, as well as with the complications. If acute rheumatism be quickly checked, inflammation of the endocardium will be also arrested; but the two diseases may recur together. In a considerable number of cases, however, endocarditis results in permanent valvular lesions.

Simple endocarditis is very rarely immediately fatal, but, being by far the most common cause of valvular disease of the heart, it leads indirectly to much suffering, and in such cases ultimately to death.

DIAGNOSIS.—The diagnosis of endocarditis depends upon the discovery of the development of an endocardial *bruit*, due to structural changes, during the course of one of the diseases already named. From functional murmurs the bruits of valvular inflammation may be diagnosed—first, by their locality, which is most frequently the mitral area; secondly, by their time, diastolic or præ systolic murmurs being always structural; and, thirdly, by their association with pericardial friction. The special characters of functional murmurs are described elsewhere (see **HEART, Functional Disorders of**). Chronic valvular disease may be diagnosed from acute endocarditis by the presence of cardiac enlargement; of cardiac failure—especially of pain and dyspnoea; of some special forms of valvular disease—mitral stenosis, for instance, being very rarely an acute lesion; and of visceral complications. Much more difficult of diagnosis is acute endocarditis occurring in the course of chronic valvular disease. Change in the character of the murmur, if this have been previously known, may lead to the suspicion of fresh inflammation, but cannot positively establish the diagnosis of its existence. Acute endocarditis is most frequently overlooked when the primary disease is 'latent'—particularly rheumatism in children.

PROGNOSIS.—The immediate prognosis of acute endocarditis is generally favourable, and may be estimated by the absence of local symptoms. The remote prognosis, on the other hand, as regards both life and health, is bad, inasmuch as endocarditis so frequently ends in chronic valvular disease. A feeble, soft, and smooth murmur is more likely to disappear than a loud, well-defined bruit. The probability of the disappearance of diastolic basic murmurs is very small; it may be best estimated by the absence of the effects produced by aortic incompetence upon the heart and vessels. Murmurs referable to endocarditis disappear more often in young subjects than in adults.

TREATMENT.—The treatment of acute endocarditis has to be discussed under three heads—preventive, immediate, and subsequent.

Preventive treatment.—When a patient is suffering from any disease which may become complicated with endocarditis, every means must be adopted to prevent its occurrence. Thus, in acute rheumatism it is all-important to check at once the intensity of the disease by recourse to one or other of the salicyl-compounds or other means; for experience shows that endocarditis, when it does occur in acute rheumatism, generally makes its appearance within the first week. Again, the duration of the primary disease must be curtailed if possible, inasmuch as endocarditis, although it generally appears early, may possibly occur at any period of the disease. Another point of equal importance in the prevention of endocarditis is diminution of the cardiac activity. We have seen that the pressure within the heart is an important factor in the causation of endocarditis; and this pressure must be reduced by diminishing the work to be done by the heart without lowering the cardiac power. Rest in the recumbent posture must therefore be enforced—an end which, except in children, is usually already secured by the presence of acute rheumatism of the joints. Excitement of every kind has to be strictly interdicted. The personal comfort of the patient must be zealously attended to, and pain relieved, so that restlessness and irritability may be avoided; and for this purpose carefully selected anodynes may be necessary. Stimulants must, if possible, be avoided; the bowels be regularly and fully moved; and the skin be kept moist.

Treatment during an attack.—When endocarditis has actually made its appearance, the various means just insisted upon must be in no way relaxed. Rest, mental as well as physical, is still of the first importance. The medicinal treatment of the original disease—especially of acute rheumatism—must be persevered in. Local applications to the præcordia, such as poultices or leeching in cases of sthenic inflammation, are often of great service. The administration of stimulants will require the greatest care; excitement of the heart, on the one hand, being avoided, and, on the other hand, digitalis, ammonia, or alcohol being employed if symptoms of cardiac distress supervene.

Treatment after an attack.—When the primary disease has subsided, and convalescence has commenced, the physician must not forget the state of the endocardium which is still the seat of active changes directed to the repair of the damaged valves. Instead of urging the patient to sit up and walk about we must recommend a very gradual return to exercise, and the most jealous avoidance of actual exertion. There can be no question that, at

this stage, rest for several weeks is of more importance than medicinal treatment. At the same time various tonic and other remedies should be employed.

Ulcerative Endocarditis.—**SYNON.** : Malignant Endocarditis; Diphtheritic Endocarditis; Fr. *Endocardite Ulcéreuse*; Ger. *Infectiose, Maligne Endocarditis*. This form of endocarditis is invariably due to infection by pathogenic bacteria.

ÆTIOLOGY.—Ulcerative endocarditis occurs most frequently between the ages of twenty and forty, but is not uncommon in children. It is more often observed in females than in males. Previous valvular disease predisposes to it, and consequently the left side of the heart is more frequently affected than the right.

The primary lesion, through which the micro-organisms enter the blood-stream, may be so slight as to escape observation; it may be situated in any portion of the alimentary, respiratory, or genito-urinary tracts, or may be a wound of the skin.

In many instances the endocarditis is but one feature of a general septic or pyæmic condition, and may then be associated with and dependent upon puerperal thrombosis, appendicitis, pyelophlebitis, acute osteomyelitis, otitis media, meningitis, gonorrhœa, lobar pneumonia, or other acute specific disease.

BACTERIOLOGY.—It is only reasonable to suppose that any of the pathogenic bacteria are capable of producing this disease, and in point of fact no less than twelve different micro-organisms have been recorded as associated causally with cases of infective endocarditis. An analysis of cases, however, shows that the most important in point of frequency are the *Streptococcus pyogenes longus*, the *Staphylococcus aureus*, the *Diplococcus pneumoniae*, and the *Gonococcus*; while the *Bacillus tuberculosis*, *Pneumo-bacillus*, *Bacillus pyocyaneus*, and *Bacillus typhosus* are also occasionally the responsible agents.

PATHOLOGY.—In infective, as in simple, endocarditis the pathological changes are limited at first to the endocardium on the margins of the valves at the seats of maximum contact during closure. The endothelial and subendothelial layers at these points are invaded by micro-organisms, which may be derived from the blood in the cardiac cavities themselves, or from the small blood-vessels of a pre-existing valvular lesion. The affected cells undergo necrotic changes, and over the necrosed area a thrombus is deposited, consisting primarily of a layer of blood-platelets, but soon converted into a 'vegetation,' by the addition of leucocytes and fibrin. Active proliferation of the cells of the subendothelial layer now takes place, leucocytes from adjacent blood-vessels infiltrate both necrosed tissue and thrombus, and if the effort at repair is effective the vegetation is gradually replaced by granulation-tissue, and finally converted into fibrous tissue. On the other hand, this cellular infiltration may result in the formation of minute abscesses in the substance of the vegetation, or, if the necrosis is the more active process, erosion and ulceration ensue, followed by perforation or complete disintegration of portions of the valve; and the resulting fragments of degenerated tissue, perhaps conveying micro-organisms, are thrown into the blood-stream to give rise to multiple emboli in distant parts of the body.

ANATOMICAL CHARACTERS.—The appearances

in malignant endocarditis are so far variable as to suggest their grouping into two types of the disease—the *ulcerative* and the *vegetative*.

In the *ulcerative* form, the endocardium presents small areas where the proper tissue has disappeared, leaving behind it shallow ragged erosions. This change occurs most frequently in connection with the mitral valves and opening, including the auricular aspect of the curtains and the line of attachment of the valves—particularly the two commissures of the segments and the anterior aspect of the anterior segment; also the aortic cusps; parts of the septum and general endocardial surface; and the papillary muscles and chordæ tendinæ. The endocardium of the right ventricle is relatively more frequently involved in malignant than in simple endocarditis.

The earliest stage of the morbid process may sometimes be observed as small yellowish opacities of the endocardium. But as a rule the surface is found already eroded, presenting a small, irregular, oval, circular, or linear ulcer; its ragged grey base covered with a loose friable thrombus; its edges fringed with vegetations, swollen, indurated, and undermined. Such an ulcer increases but slowly in area, but it readily advances into the depth of the tissue. A variety of secondary changes may then occur—acute valvular aneurysm, complete perforation of the valves, abundant vegetative or fungating growths, and suppuration, which ends in acute cardiac aneurysm or in complete perforation of the parietes.

The *vegetative* form of malignant endocarditis is readily recognised *post mortem* by a prominent and possibly extensive growth of polypoidal vegetations, in connection usually with the auriculo-ventricular opening, the neighbouring surface of the left auricle, and the auricular aspect of the mitral segments. Less frequently the aortic valves are involved. In either situation the vegetations form a large mass of soft growth, almost choking the mitral or aortic opening, while portions of it must have floated and waved in the blood-current, and by their contact or impact during the cardiac movements have injured the neighbouring or opposed surfaces of the endocardium, there setting up fresh disease of the same kind. The surfaces of these vegetations are sometimes calcified.

In both forms of malignant endocarditis it is obvious that during life portions of the diseased endocardium and thrombi, as well as their fluid products, whether on a small or on a large scale, must have been readily detached or washed off, and carried as emboli into other parts of the circulation.

In addition to the lesions just described, the heart may present a variety of morbid changes. It is in at least 75 per cent. of cases (Sansom) the seat of chronic valvular disease and associated enlargement, sometimes of congenital malformation. The myocardium may be swollen and in a state of granular degeneration like other visceral structures; or it presents a number of small embolic, hemorrhagic, inflamed, or fattily degenerated areas. Pericarditis is sometimes associated.

Embolism is one of the essential accompaniments of ulcerative endocarditis. It occurs most often in the spleen, kidneys, and heart, but may be almost universal. In the vegetative form of the disease the emboli may be so large as to be arrested even in the abdominal aorta; the tibial, brachial, and other vessels of the limbs are often occluded, as well as the splenic, renal, mesenteric, cerebral, and a

variety of arteries in other parts of the body. In the purely ulcerative type of the disease the emboli are much smaller, and their effects are only recognised *post mortem* by infarcts in various conditions of change. These secondary foci often proceed to abscess-formation—suppurative meningitis is fairly common. The skin and mucous membranes, the serous membranes, the vessel-walls, and the retina are also favourite seats of minute embolism and hæmorrhage. The lungs are specially affected in some cases; pulmonary embolism and infarction accompany ulcerative endocarditis of the right chambers; in other instances acute pneumonia appears to be the primary lesion, in which the endocarditis of the left chambers of the heart has originated. The local effects of infective embolism occur very extensively in ulcerative endocarditis, namely, hæmorrhage, softening, and acute aneurysm ending in fatal rupture. See EMBOLISM.

SYMPTOMS.—In its clinical characters malignant endocarditis is either (a) an *acute*, severe, and fatal malady with markedly typhoidal features; or (b) a disease of *sub-acute*, *possibly chronic*, course, pyæmic in character, occasionally ending in recovery. These two forms call for separate description.

(a) **Acute Typhoidal Malignant Endocarditis.**—In this variety of the disease, the patient is seized with a rigor when apparently in good health, or during convalescence from an acute illness—particularly rheumatism; in other instances the invasion is more gradual. Pyrexia and the other phenomena of severe fever are quickly developed, and the patient complains of malaise, debility, and cardiac distress; but for the first two days the medical attendant probably fails to make a complete diagnosis. By the end of this time, the patient's condition having become steadily worse, the cardiac sounds are found to be impure; they shortly become murmurish; and probably on the next day an endocardial murmur is developed, systolic or diastolic, still changeful in its characters. The general symptoms now begin to assume a typhoid type. The patient lies helplessly on his back; the temperature rises to 104°; the tongue, at first furred, becomes dry and brown; sordes form; the respiration becomes hurried, possibly with thoracic pains and hæmorrhagic sputa; and somnolence sets in, broken by low muttering delirium, jactitation, and subsultus. The spleen is enlarged and tender, suggesting infarction. The bowels may be relaxed. The skin is visited by heavy sweats, and may become covered with a peculiar petechial eruption. The urine, passed naturally or incontinently, or withdrawn with the catheter, is found to contain blood, albumen, and occasionally micro-organisms. The ophthalmoscope reveals retinal and other intra-ocular hæmorrhages. Bleeding takes place from the bowel. Less frequent symptoms are parotitis, arthritis, pericarditis, and jaundice. Meningitis, associated with headache and delirium, and ending in coma, is more common, and gives a new or different aspect to the case.

Malignant endocarditis of this severe type may be said always to terminate in death after a duration of less than fourteen days; it has been known to end fatally in two days. The course which the disease pursues is one of steadily increasing gravity, broken only by equally ominous complications in the form of meningitis, hæmorrhages, or sudden paralysis referable to cerebral hæmorrhage. Very rarely the disease passes into the subacute or chronic form.

The pyrexia belongs to the continued type, the maximum rise being 104° or 105° F., with a daily remission of about one degree. In some instances it may not exceed 101° , or may even keep close to normal. With the fever may be associated repeated rigors, followed by increased prostration and stupor. The physical signs connected with the heart have already been referred to. The endocardial murmur is usually systolic and mitral. It develops under observation, changes in loudness and quality day by day, and may be reinforced by a second murmur over another part of the præcordia. If traced to the right side of the heart, it is of special significance. Occasionally the murmur is absent, suggesting a parietal lesion. The radial pulse presents all the characters of the typhoid state with increasing prostration, rather than those of any particular form of valvular disease. The so-called cutaneous 'eruption' consists of fine reddish spots, each with a paler centre representing the seat of a minute embolus. The signs of pleurisy, pulmonary infarction or gangrene, or even of pyo-pneumothorax, are sometimes to be determined.

(b) **Subacute and Chronic Malignant Endocarditis.**—This variety of the disease bears but little superficial resemblance in its clinical characters to the severe form just described. Its general features are those of subacute or chronic cardiac disease accompanied by pyrexia and multiple embolism. Heart-disease is the central fact, to which are superadded the phenomena of general infection. There is no prostration until the last; no typhoid aspect. The patient is anæmic, sallow, poorly, and he wastes steadily; but he sits up in bed, reads, engages in conversation intelligently and cheerfully, and may even resent strict treatment. The physical signs connected with the heart consist mainly of a well-developed endocardial murmur, possibly referable to a previous valvular lesion, but changing its characters from time to time under observation. It is usually systolic and mitral; occasionally aortic systolic or diastolic, or mitral præ-systolic; and it may be suddenly altered or complicated by the development of a fresh lesion in the heart, such as rupture or perforation. The pulse varies greatly.

The type of pyrexia in fully developed cases of malignant endocarditis of subacute course is markedly remittent, or even intermittent. Three, four, or even six degrees F. of a rise and fall (between 98° and 102° to 104°) may be recorded daily for weeks on end. In other instances the disturbance of temperature takes the form of irregular bouts of pyrexia complicating the downward course of a severe case of valvular disease. Some patients suffer from repeated rigors, unexpected and irregular, followed by profuse sweats and prostration.

The other phenomena of general infection are mainly significant of embolism—pain and the proper physical signs of infarction of the spleen and lungs, blood in the urine, loss of pulsation in the arteries of the limbs, the development of acute aneurysm with subsequent rupture, and even gangrene of the extremities. This element of the disease gives it a peculiarly uncertain and protean character, its course being, for instance, suddenly interrupted by the development of severe hæmorrhage into the peritoneal cavity, or possibly into the brain, with paralysis and coma ending in rapid death.

The duration of this disease is almost indefinite. It has extended from six or eight to twelve or sixteen weeks—in one case eighteen months. The

progress is very striking. The patient steadily but almost imperceptibly loses strength, flesh, and colour. With very few exceptions, the disease terminates in death, and such patients as have recovered have been left with permanent heart-disease.

DIAGNOSIS.—The acute form has to be diagnosed from typhoid fever, acute tuberculosis, and other infective diseases belonging to the same type. The diagnosis usually turns on its association with some primary disease, and on the result of a physical examination of the heart and the correct interpretation of any murmur that may be discovered. When no murmur is developed, ulcerative endocarditis may escape recognition. Repeated rigors, the type of pyrexia, the character of the spots, and the occurrence of retinal hæmorrhages will further serve to exclude typhoid fever and tuberculosis. When delirium and other cerebral symptoms are urgent, ulcerative endocarditis has been mistaken for 'cerebral rheumatism' and simple meningitis.

The subacute and chronic forms are specially liable to be confounded with a number of diseases which present a similar type of pyrexia, particularly the many pathological conditions which underlie obscure persistent pyrexia, such as latent tuberculosis; lymphadenoma; chronic suppuration in connection with the liver, prostate, bowel, kidney, internal ear, lymphatic glands, and connective tissues; and also syphilis. The existence and changeable character of the murmur, the sudden embolisms, and the absence of other local signs, all indicate the cardiac seat of the disease. From malaria it can be distinguished by the history, by the absence of periodicity in the rigors and fever, as well as by the cardiac murmur.

Some of the gravest complications of this form may, for a moment, be misleading, such as violent headache ending in coma, referable to the development and rupture of embolic intracranial aneurysm. Experience teaches us to be prepared for every possible variety of symptom in a disease of which a striking feature is visceral embolism.

The examination of blood taken during life is frequently of assistance in diagnosis, by showing the presence of micro-organisms. Great care must be exercised in sterilising the skin, instruments, &c., and as the bacteria are never present in large numbers in the peripheral circulation, several cubic centimetres of blood should be collected and many cultivations prepared. It may be necessary to withdraw the blood from a vein by means of a sterile syringe, especially in cases of suspected gonococcal infection, when the blood should be mixed with melted agar-agar (cooled down to about 40° C.) and plate-preparations poured from the mixture, before leaving the bedside.

PROGNOSIS.—The prognosis was formerly hopeless. Almost the only chance of recovery lies in the efficacy of the anti-toxin treatment described below.

TREATMENT.—The gravity of acute ulcerative endocarditis impresses on us the importance of preventive treatment. Dr. Sansom urges the necessity of protecting the subjects of chronic valvular lesions against zymotic diseases, and of attending to the treatment of suppuration with special care. In some instances the primary disease or source of infection can be dealt with remedially, and the attempt should always be made to do so. The mouth, for example, should be cleansed several

times daily ; and it is an absolute rule of practice to secure at least one complete evacuation of the bowels in twenty-four hours.

The most useful and by far the most promising method of treatment for ulcerative endocarditis consists in serum-injections (*see* ANTITOXINS ; and SERUM-THERAPEUTICS). A serum indicated by the results of bacteriological investigation of the blood should be administered freely until its antitoxic action has been proved or disproved ; and in the latter event other serums, or even other brands of the same serum, should be tried.

Many drugs have been given in this disease, unhappily with little benefit, including mercurials, quinine and other antipyretics, and the essential oils of eucalyptus, turpentine, and their allies. In a few instances of the acute form success appears to have followed the use of sodium sulphocarbolate (30-grain doses four times a day), and quinine (15-grain doses three times a day with a free allowance of alcohol).

The case must be managed on the general principles applicable to all acute specific fevers. The best possible nursing, abundance of food, and a sufficient supply of stimulants will be provided. Fresh air is essential. If the disease be traced to defective sanitation, it may be advisable to take the risk involved in changing the room, or even the house, in which the patient is lying. Indeed, in every case it is advisable to move the patient from the room in which he has been ill for some time.

J. MITCHELL BRUCE.

HEART, Inflammation of Walls of. —

SYNON. : Myocarditis ; Carditis ; Fr. *Myocardite* ; Ger. *Myocarditis*.

This disease may be either acute or chronic ; but the latter form, which is attended by the formation of fibrous tissue in the myocardium, is described under the head of HEART, Fibroid Disease of.

Suppurative Inflammation.—Abscess of the heart has been most frequently observed in cases of pyæmia following acute necrosis of bone or diffuse periostitis ; less frequently after phlebitis, chronic or acute arthritis, urethral stricture, chronic abscess, and cancerous ulceration. It occurs most frequently in cases following injury to a bone or a joint in boys. In older subjects it has generally been associated with pyæmia secondary to one or other of the diseases just mentioned. The pyogenic organisms may reach the myocardium by way of the coronary vessels or directly from an infective ulcer in the endocardium.

ANATOMICAL CHARACTERS.—The left ventricle—towards the base and in the papillary muscles—is most commonly affected. Pericarditis co-exists in the great majority of cases, and very frequently endocardial inflammation as well. Pyæmic foci are generally multiple, and vary in size from a pea to a pin's head. They appear at first as small, slightly elevated, yellowish or buff-coloured softened patches, projecting either on the external or on the internal surface of the heart, and covered with inflammatory deposit. On section, these patches either present an appearance of diffused yellowish softening, or contain one or more collections of dark dirty puriform matter, with ragged ill-defined boundaries, as if formed by destruction of the discoloured tissue around. When due to extension from an endocardial ulcer there may be a single abscess, often of larger size than those just described.

Microscopically examined ; the yellowish patches prove to be portions of the myocardium which are infiltrated with pus and consist of necrosed or degenerated muscular tissue and various bacteria. The several stages of the pyæmic process have been found side by side in some cases ; and infective emboli have been discovered in the branches of the coronary arteries, where they served as the foci of the abscesses. The walls of the heart are sometimes in a condition of softening throughout. Abscess of the heart occasionally bursts ; and the contents make their way either into the left ventricle—producing cardiac thrombosis and aneurysm, and perhaps giving rise to further embolism and pyæmic disease—or into the pericardial sac.

SYMPTOMS.—Whatever the symptoms of pyæmic abscess of the heart may be, they are obscured by the general symptoms of the primary disease, and by the local symptoms and signs of pericarditis. Thus, the patients are described as presenting a febrile, typhoid, or pyæmic appearance, an anxious look, dyspnoea, and præcordial pains ; and pericardial friction has generally been discovered over the heart. Rigors have been observed in some cases ; and a peculiar pustular eruption on the skin in other cases. Delirium probably occurs more frequently than in ordinary cases of pyæmia, but may be referable to the accompanying pericarditis. The *physical signs* found in these cases are chiefly those of acute pericarditis. Sometimes an endocardial bellows-murmur may be heard, due either to valvular lesion, or to the formation of an acute aneurysm of the cardiac wall.

The majority of cases of abscess of the heart prove fatal by asthenia ; but the other terminations of abscess mentioned above will be attended by their respective symptoms, and the possibility of sudden death is especially to be noted.

Parenchymatous Inflammation.—This term is used to designate a form of acute myocarditis associated with acute endocarditis and pericarditis, and depending upon the same causes, the most frequent being acute rheumatism. In a small proportion of cases, rheumatic myocarditis appears to occur independently of inflammation of the lining or of the covering membrane. It has been observed most frequently in males, and before the twenty-fifth year of life. Exposure to cold, severe exertion, and local injury are mentioned among exciting causes, but with questionable correctness.

ANATOMICAL CHARACTERS.—The ordinary form of the disease is characterised by the appearance of leucocytes between the muscular fibres of the heart. In one class of cases the inflammation is moderate in intensity and confined to one or more layers of muscle underlying the endocardium or the pericardium, which is also inflamed ; in another class of cases the inflammation is more diffuse, affecting the muscular walls generally.

The myocardium, as it is seen through its inflamed covering, appears of a mottled opaque buffy colour, and is somewhat swollen and softened. The microscopical characters consist chiefly in the appearance of micro-organisms, leucocytes, and inflammatory effusion in the peri-vascular intermuscular connective tissue ; swelling, opacity, coagulation-necrosis, rupture and fatty degeneration of the muscular fibres ; and the ordinary inflammatory changes of the vessels of the part. Beyond this stage, unless the case prove fatal, the diffused form of myocarditis passes into a chronic condition ; and it ends either in

fibroid disease with a moderate amount of atrophy, by development of the inflammatory products and compression of the affected fibres; in fatty degeneration; in calcification; or in cardiac aneurysm.

In all forms of interstitial myocarditis the left ventricle is most frequently the seat of inflammation.

SYMPTOMS.—The principal symptoms of acute rheumatic myocarditis are restlessness and urgent dyspnoea; severe pain and distress referred to the præcordia; and palpitation, which gradually passes into irregularity and greatly increased frequency, and finally into complete cardiac failure. The pulse corresponds. The countenance is anxious, and either pale or cyanosed. The mind is fearful and distressed at first; and delirium frequently supervenes before death, especially in young subjects. Vomiting is not uncommon. The *physical signs* are generally associated with those of endo- and pericarditis. When uncomplicated, they may be described as consisting of violence of the cardiac impulse at first, which rapidly loses in strength and regularity while it increases in frequency; increased area of præcordial dullness; and short sharp sounds, afterwards becoming duller and more feeble. When these symptoms and signs make their appearance, they generally run their course rapidly, and end in death. In a small number of cases they as rapidly disappear.

COMPLICATIONS.—The complications of acute myocarditis have already been sufficiently indicated, including, first, ætiologically, pericarditis, endocarditis, acute rheumatism, and other causes of these forms of inflammation; and secondly, pathologically, rupture of the cardiac walls or valves, acute cardiac thrombosis, aneurysm, hæmato-pericardium, embolism, and septicæmia.

COURSE AND TERMINATIONS.—The course of acute interstitial myocarditis, as already stated, is generally rapid, extending from a few hours to eight days in different cases. Death occurs, in the great majority of cases, from the effects of cardiac failure, if the inflammation be extensive or proceed to supuration. The formation of acute aneurysm by internal rupture, the production of pericarditis by external rupture, and other complications will variously modify the progress and termination of cardiac abscess. Simultaneous rupture both externally and internally causes sudden death.

DIAGNOSIS.—The diagnosis of acute myocarditis is extremely difficult. Occurring in connection with acute rheumatism, it has to be distinguished from endo- and pericarditis. The absence of murmur and of the characteristic signs of pericarditis, along with symptoms of cardiac failure and severe local phenomena, such as pain, distress, dyspnoea, and finally collapse, should generally serve to establish the diagnosis of inflammation of the walls of the heart. It cannot be said that cardiac abscess has ever yet been diagnosed; but the careful consideration of all the points in the case, including the sudden development of a murmur indicative of rupture of a portion of the wall, or of a valve, may hereafter ensure greater success. In the event of the development of the last-named sign, and of septicæmia or embolism, cardiac supuration would have to be carefully diagnosed from ulcerative endocarditis, with which it is often associated. In children, the delirium of acute myocarditis has to be distinguished from that of acute meningeal inflammation, an object which may be effected by the careful observation

of the signs and symptoms connected with the heart.

The diagnosis of pyæmic abscess must largely depend on the discovery of some source of infection.

PROGNOSIS.—The prognosis of myocarditis, when it is either so extensive or so intense as to give rise to unequivocal symptoms, is extremely unfavourable.

TREATMENT.—The two principal indications of treatment in acute inflammation of the substance of the heart are to rest and sustain that organ, and to relieve the pain and distress. Local anodynes, especially in the form of the preparations of belladonna and poultices, and stimulating counter-irritants, such as mustard poultices, will conduce to fulfil the second indication. Such relief is essential, if rest is to be secured. The patient must be spared the very smallest exertion. Food must be given in small quantities, and be easily digestible and highly nutritious; the bowels must be kept open; and the flow of urine should be as free as possible. Alcoholic stimulants will be urgently called for, but must be employed with great discrimination; and palpitation, as much as weakness of the impulse, is to be regarded as an indication of the necessity for these. At the same time, digitalis, ammonia, and other cardiac stimulants should be given cautiously, so as to sustain the cardiac action.

J. MITCHELL BRUCE.

HEART, Malformations of.—**SYNON.** : Congenital heart-disease; Morbus Cœruleus; Fr. *Affections congénitales du Cœur*; Ger. *Missbildungen des Herzens*; *Angeborenen Herzerkrankheiten*.

DEFINITION.—Defects in the structure of the heart due to arrest or perversion of the normal process of development.

Development of the Heart.—The heart develops from a single tube, formed by the fusion of the two original symmetrically placed blood-vessels, found in the early developing embryo. This tube receives at its hinder end the two large omphalo-mesenteric veins, and terminates anteriorly in the aortic bulb, which divides into two branches, the two primitive aortæ. The originally straight tube soon becomes bent upon itself in the form of a U, so that the portion into which the veins enter is brought into apposition to the origin of the aortæ. Constrictions appear in the tube, partially dividing it into four compartments—the hindmost, into which the veins enter, being the sinus venosus, the next the auricular portion, the third the ventricular cavity, and the fourth the aortic bulb. The auricular and ventricular portions enlarge, but are not in their early stages complete cavities, the interior being occupied by a sponge-work of muscular fibres, some of which ultimately disappear, while others take part in the formation of the septa or persist as columnæ carneæ and musculi papillares. In order that the double circulation of mammalian animals may be established, it is necessary that the single tube should be divided longitudinally into a double series of chambers. The process by which this is brought about is somewhat complicated. The orifice leading from the auricular into the ventricular cavity becomes elongated into the form of a slit: two out-growths from the heart-wall appear, situated one on each side of this slit about the middle of its length, and these meet and fuse with one another, thus dividing the orifice into two separate channels. A similar out-growth takes place from the hinder

(upper*) part of the auricular cavity; and this, growing forwards (downwards) as a septum, meets the partition formed in the auriculo-ventricular orifice and fuses with it. In the same way a partition grows backwards (upwards) from the apex of the ventricular cavity and coalesces with the others near their point of fusion. In like manner, by means of longitudinal ridges which arise along the walls and ultimately fuse together, the single aortic bulb is divided into two vessels, the aorta and the pulmonary artery, the line of division becoming, by torsion of the tube, somewhat spiral, so that the pulmonary artery which is connected with the right ventricle below crosses the aorta to lie on its left side above. This last septum coalesces with the others at its hinder (lower) end, sending a short prolongation forwards (downwards) to meet and complete the ventricular partition. The formation of the foramen ovale in the auricular septum is a secondary process: a number of small holes appear in the septum and coalesce so as to form a single channel. An endocardial fold grows over this aperture and at first acts as a valve: subsequently it becomes attached along the margin of the foramen and entirely closes it after the birth of the child. The ductus arteriosus—the communication between the aorta and the pulmonary artery—becomes obliterated before the end of the third week of extra-uterine life.

Varieties of Malformation.—Defects may occur in the formation of any of the septa above mentioned, or in the development of the valves at the orifices of the great vessels. These vessels are occasionally transposed, so that each communicates with the opposite ventricle to that with which it is normally connected. The foetal channels—the foramen ovale and the ductus arteriosus—may also fail to close, as they normally do, after birth. It is to be remarked that this last class of defects cannot rightly be described as congenital, since the failure in development occurs after the child is born. In the majority of cases several malformations co-exist in affected hearts, one abnormality counteracting to some extent the disturbance in the circulation brought about by the other.

A. Defects in the Primary Septa:

1. In rare cases *absence of all the septa* is met with, and the heart remains a single tube divided into auricle, ventricle, and aortic bulb. The condition produced is similar to that normally existing in fishes.

2. *Absence or Defect of the Ventricular Septum.* Complete absence of the septum between the ventricles is occasionally found, the heart possessing two auricles and one ventricle, as in the frog. Partial absence of this septum is not uncommon, the most usual seat of the defect being the portion separating the upper parts of the ventricles—the so-called ‘undefended space.’ In the hearts of children, and less easily in those of adults, it may be seen that this portion of the septum is thin and membranous, not being strengthened by muscular fibres, as is the rest of the partition. Occasionally the weakness of this part of the septum is shown by the formation of an ‘aneurysm of the undefended space,’ projecting into the cavity of one of the ventricles. Rarely other parts of the septum may be absent, allowing

communication between the two ventricles. If the extreme upper portion of this septum be wanting, a passage may even be left open between the origins of the aorta and the pulmonary artery.

3. *Defects in the Auricular Septum* (apart from patency of the foramen ovale) are occasionally met with. The commonest situation of such defect is the anterior (lower) portion of the septum, which is formed last, and normally fuses with the septum of the auriculo-ventricular orifice.

4. *Defects in the Septum of the Aortic Bulb.*—Complete absence of the arterial septum may be found in connection with defect in the ventricular partition. The more common malformations are caused by irregularities in its position. Thus the lumen of the pulmonary artery may be so far encroached upon as to leave this vessel very narrow (*stenosis*) or quite impervious (*atresia*), the aorta being consequently much larger than usual, and connected in many cases with both ventricles. Conversely, but much more rarely, the aorta may be narrow or obliterated and the pulmonary artery unusually large. Another defect that is occasionally found is the connection of the aorta with the right ventricle, and of the pulmonary artery with the left (*transposition of vessels*).

B. *Defects in the Valves* at the orifices of the great vessels are not infrequently found. Thus, instead of three semilunar valves only two may be present, or a single membrane with a central perforation may represent the valves. Such fusion is probably the result of foetal endocarditis. In other cases additional valves are formed, so that four or even five pockets exist, but the additional segments generally remain rudimentary. Small congenital perforations of the valves are not very uncommon.

C. (1) *Patency of the foramen ovale.*—It is not very rare to find *post mortem*, even in individuals who have shown no symptoms of cardiac disease, a small aperture, corresponding to part of the foramen ovale, by which communication between the two auricles is produced. Larger defects, permitting free interchange of blood between the right and left hearts, are generally accompanied by the usual signs of congenital malformation, and are often associated with other cardiac deformities.

(2) *Patency of the ductus arteriosus* is also most frequently found in connection with other varieties of congenital defect.

D. *Formation of additional septa* is not a common abnormality. The appearance of an imperfect second septum in the right ventricle has been described, the aorta also arising partly from this ventricle. The condition resembles that normally found in the turtle, in which animal there are two aortic ventricles and one pulmonary.

E. *Fissure of apex.*—The slight depression sometimes found corresponding to the division between the two ventricles at the apex of the heart may be exaggerated, so that the apex of the organ appears bifid or mitre-shaped. A similar condition is said to occur normally in the dugong.

F. *Complete absence of the heart* (acardia) is met with in foetal monstrosities. It is, of course, incompatible with extra-uterine life.

COMBINATIONS OF DEFECTS.—Stenosis of the pulmonary artery, one of the commonest malformations, affords a good instance of the interdependence of cardiac anomalies. Since the blood cannot reach the lungs in sufficient quantity through the narrow

* The expressions ‘forwards’ and ‘backwards’ refer to the position of the original cardiac tube which lies longitudinally in the embryo: the words in brackets express the relations existing in the fully formed heart in the upright position.

trunk, an additional supply must be brought from elsewhere. For this purpose the ductus arteriosus generally remains patent, so that the aorta may supply the defect. At the same time the pressure existing in the right heart, owing to the narrowness of its arterial outlet, needs relief, which is afforded either by continued patency of the foramen ovale, or by a defect in the ventricular septum, situated generally at the undefended space. Stricture of the trunk of the aorta, either at its origin or, as more frequently happens, close to its junction with the ductus arteriosus, is similarly remedied by the patency of this latter vessel. In the event of total atresia of either great vessel occurring, the ventricle from which it arises atrophies to a great extent from want of use. In cases of stenosis, on the other hand, the ventricle hypertrophies and dilates behind the obstruction. In many hearts in which the pulmonary artery is stenosed, the aorta is correspondingly enlarged and communicates with both ventricles, thus receiving an additional quantity of blood and relieving the pressure in the right heart.

ÆTIOLOGY.—Two distinct, or partially distinct, causes appear to be at work in the production of cardiac malformation. It may be due, on the one hand, to some defect in the developmental energy of the embryonic cells, similar to that whereby defects are produced in other parts; the nature of this failure of energy is not clearly understood. On the other hand, endocarditis, identical with that occurring in post-natal life, may affect the heart of the foetus while still unborn, and may cause perversion of the process of development. Thus inflammation of the endocardium within the trunk, or at the orifice, of the pulmonary artery may cause stenosis or obliteration of this vessel; while endocarditis affecting the undefended space may cause weakening of this part and lead either to the formation of an aneurysm or to actual defect in the septum at this point. It must be admitted, however, that the rheumatic poison, circulating in the blood of the mother, may not only cause endocarditis in the foetus, but may be not altogether unconnected with certain cases which appear to be due to unexplained errors of development. It has been found in experiments upon fertilised eggs, that not only such external interference as incubating them in abnormal positions or varnishing parts of the exterior may produce defects in the development of the chicks; but that the injection of poisons, such as the toxins of bacteria, may have the same result. It is therefore highly probable that many congenital abnormalities may really be due to toxins in the mother's blood, which have poisoned the growing cells of the embryo and caused them to develop irregularly or defectively. The rheumatic poison is a very probable agent of this nature, as are also the poisons of the acute specific fevers and other diseases. It is known indeed that many of these may cause death of the foetus and consequent abortion; a smaller dose may act only on individual cells and impair their subsequent development. The 'selective' action of certain toxins upon particular tissues would conceivably hold good in the embryonic stage of these tissues, and the rheumatic poison which affects the endocardium in extra-uterine life might act on the same tissue before birth. When once any primary defect has been produced, the resulting disturbance in the blood-pressure within the cavities of the heart will tend to cause secondary malformations, such as patency of the foramen ovale

or defect in the ventricular septum, by which some degree of compensation is effected.

CLINICAL PHENOMENA.—The subjects of congenital defects of the heart are, as a rule, weak and sickly. They are handicapped in the race of life and succumb readily to adverse conditions. Thus they are very susceptible to cold, and prone to develop bronchitis and tuberculosis of the lungs. Many infants suffering from this form of malady perish from convulsions. The disturbance produced in the circulation of the blood by the various lesions results in the appearance of murmurs, which present sometimes very characteristic features. They are generally systolic in time, but may be diastolic, or may not correspond exactly with either sound in the ordinary cardiac cycle. They are generally loud and harsh in quality, and are audible over a great part of the præcordium, or even over the whole chest.

Three special phenomena are associated with cardiac malformations—cyanosis, clubbing of the fingers, and concentration of the blood. *Cyanosis*, or blueness of the face and extremities, is in many cases a very marked feature. It may exist from the moment of birth, the term 'morbus cæruleus' being applied to the condition presented by infants so affected. In other cases it is slight and may be only manifested on exertion. The nose, ears, and lips in severe cases are of a deep blue, or almost black, colour, while the rest of the face and the hands and feet are livid and dusky. The circulation in the parts appears slow and defective. No entirely satisfactory explanation has been given of this phenomenon. It has been held (1) that it is due to mixture of venous and arterial blood; but this explanation cannot be maintained in face of the facts that cyanosis may be present in cases in which no communication between the right and left hearts is found, and absent in others where free admixture of blood exists. (2) Deficient aëration of the blood owing to defective circulation through the lungs is possibly a factor in some cases, but cannot sufficiently explain all. (3) Venous congestion, owing to defective action of the heart and consequent over-filling of the veins, is also a probable cause of some at least of these cases, while in addition to this (4) the concentrated condition of the blood causes any defect of oxygenation, and any tendency to stagnation in superficial parts, to be manifested by a deeper colour than would be produced under normal conditions.

Clubbing of the fingers and toes is usually present along with cyanosis, and absent when this is not found. The cause of its appearance is also doubtful, but it is probably due to congestion of the extremities, arising from defective circulation and leading to increased formation of connective tissue. The nose in some cases is also bulbous. See p. 548.

Concentration of the blood may reach a very considerable degree. Thus the specific gravity may rise to 1070 or 1080, and the number of red corpuscles may be augmented to over eight millions in each cubic millimetre, the hæmoglobin being increased by as much as one tenth of the normal amount (110 per cent.). It has been suggested that this increased richness of the blood is due to diminished wear and tear of the corpuscles, owing to defective circulation, especially through the lungs. Little is known, however, at present of the life-history of the blood-corpuscles under normal conditions, and the whole subject awaits further elucidation.

In many cases of congenital heart-disease none of these characteristic phenomena are present.

DIAGNOSIS.—Two points have to be determined in relation to congenital deformity of the heart: (1) the existence of a malformation, and (2) the nature of the lesion. With regard to the former point, it necessarily happens, owing to the tendency of these conditions to shorten life, that the patients in whom the diagnosis has to be made are generally children. If the typical signs—cyanosis, clubbing, and cardiac murmurs—are present, the diagnosis of congenital malformation is easily made. If, however, these are absent, great difficulty may arise. The presence of a cardiac murmur in a very young infant is very suggestive of congenital defect. In rather older children the co-existence of a loud murmur with a præcordial impulse which is either feeble or normal in strength usually points to the existence of malformation, since the various forms of acquired disease rapidly produce in children hypertrophy of the heart, and consequently an increased force of contraction. The increase in the size of the heart, due to post-natal endocarditis, generally results also in some bulging of the præcordial region, which is absent in congenital cases. Congenital stenosis of the aorta—a rare condition—may, however, give rise to hypertrophy of the left ventricle, and narrowing of the pulmonary artery is accompanied by enlargement of the right side of the heart. The murmurs caused by congenital disease of the heart are more frequently basic than apical, and in the majority of cases are systolic in time; they are frequently very loud and harsh—out of proportion to the enlargement of the heart and force of the impulse—and may be audible all over the præcordia and, indeed, all over the thorax. It must be borne in mind, however, that in anæmic children hæmic murmurs at the base of the heart are not at all uncommon; these, however, are not accompanied by a thrill, which may, or may not, be present in cases of malformation. A weak pulmonary closure-sound along with an apical murmur is suggestive of cardiac deformity, the pulmonary sound in children being normally accentuated.

In the majority of cases it is not possible to determine the exact nature of the deformity present. As already mentioned the commonest malformation of the heart consists in a *narrowing of the trunk of the pulmonary artery*, generally combined with a compensatory enlargement of the aorta and patency of the foramen ovale. This condition is typically accompanied by cyanosis and by a loud systolic murmur, audible over a wide region, and having its point of maximum intensity in the second left intercostal space near to the border of the sternum. Signs of enlargement of the right side of the heart may be present, but the pulmonary closure sound is not accentuated, and may be unduly weak. *Patency of the foramen ovale* may give rise to no physical signs whatever in slight cases: in others it may be accompanied by cyanosis and by the presence of a murmur, which is generally systolic in time, but may occupy any position in the cardiac cycle. *Defects in the ventricular septum* are said to give rise to loud systolic murmurs without any accompanying thrill. A basic murmur going along with a well-marked thrill, in a heart which shows no sign of hypertrophy, may be indicative of *persistency of the ductus arteriosus*. The thrill is often very prolonged in these cases, lasting well into the diastolic period. The murmur may

be found to begin distinctly after the systolic impulse. Cyanosis and clubbing of the fingers are often absent in cases of this deformity. *Congenital stenosis of the aorta* is marked by similar signs to those which accompany the condition when it results from post-natal disease. The left ventricle is hypertrophied and a systolic murmur, well conducted into the vessels of the neck, is audible. A thrill may or may not be present. In those cases in which obliteration of the vessel takes place near to its junction with the ductus arteriosus—a condition generally treated as a cardiac malformation—signs of the formation of a collateral circulation may be evidenced by the presence of dilated subcutaneous arterial trunks. In cases of *transposition of the aorta and pulmonary artery* no murmur is likely to be audible, but the second sound of the heart is much exaggerated in the pulmonary region, and cyanosis is generally well marked.

PROGNOSIS.—Speaking generally the outlook in all cases of congenital heart-disease is bad, the great majority of patients thus affected failing to reach adult life. In particular instances any forecast of the probable course of the case must be guided rather by the general features manifested than by any reliance upon a power of ascertaining the exact nature of the lesion: the degree of cyanosis of the face and extremities, the amount of dyspnoea occurring on any exertion, and the presence or absence of associated pulmonary disease constitute the main guides available for forming an opinion. The circumstances of the patient must also be taken into account, since the subjects of cardiac malformations need most careful attention and the most favourable surroundings to enable them to survive. With regard to the different varieties of defect, it appears that patency of the foramen ovale is the least serious, since small degrees of this malformation are compatible with the attainment of advanced age. Defects in the ventricular septum come next in order of severity, life being occasionally prolonged to the adult period. Cases of pulmonary stenosis may also rarely reach adult age, but the majority die in childhood. Patients suffering from total atresia of this artery, or from transposition of the aorta and pulmonary artery, seldom live many months. Fœtuses, the subjects of atresia of the aorta, are seldom viable, and stenosis of this artery, if congenital and affecting the orifice of the vessel, is generally rapidly fatal. Stenosis occurring at the junction of the ductus arteriosus is less unfavourable, and is even compatible with the attainment of adult life. Rupture of the aorta may be the ultimate cause of death in such cases. Tuberculosis occurring in patients suffering from cardiac deformity is likely to progress rapidly to a fatal issue.

TREATMENT.—Present knowledge of the causation of congenital deformities is not sufficient to indicate any definite prophylactic measures to be taken by the pregnant woman. It is necessary to guard carefully against infectious diseases, and to have immediate recourse to treatment should any symptoms of rheumatism be manifested. The importance of observing with additional care during pregnancy all the ordinary rules of personal hygiene should be impressed upon the future mother. In children who are the subjects of congenital heart-disease nothing can be done to remedy the deformity. Treatment must be directed to making the surroundings of the patient as favourable as possible. Cold is particularly to be guarded against. Cloth-

ing should be warm and suited to the season of the year. It may be advisable to spend the winter in some warm climate. Unnecessary exertion of all kinds is to be avoided, the occurrence of dyspnoea giving warning in individual cases of the attainment in this respect of the limit which should not be overstepped. The risk of tuberculosis should be minimised as far as possible by maintaining a continual supply of fresh air—without chilling the patient—and by seeing that the food is plentiful and digestible. Residence should, if possible, be in a warm dry locality, upon a gravelly soil. The existence of a family tendency to rheumatism makes all the above precautions even more urgently necessary. Failure of the heart, when it occurs, must be treated on ordinary lines: there is no contra-indication to the use of digitalis and the other cardiac stimulants in these cases. The slightest symptoms of bronchitis must be at once recognised and the condition treated. It is scarcely necessary to insist that the subjects of congenital deformity of the heart should be advised not to marry. The slighter degrees of malformation are not necessarily incompatible with occupations involving no muscular exertion and no special liability to exposure to cold and wet. W. CECIL BOSANQUET.

HEART, Morbid Growths in.—The morbid growths that have been met with in the heart may be thus enumerated in the order of their frequency: (1) Secondary tumours, especially carcinoma; (2) Primary sarcoma and lympho-sarcoma; (3) Non-malignant tumours; and (4) Cysts.

Malignant Disease.—Malignant disease of the heart is very rare, and is generally secondary. Occasionally the heart becomes involved by continuity, the lungs and mediastinum having been primarily affected. Cases have occurred at all periods of life, from infancy to old age; but at least one half of the subjects have been in the middle period of life. The disease is most frequent in males.

ANATOMICAL CHARACTERS.—Carcinoma, epithelioma, and sarcoma have all been found in the heart in different instances. The right side appears to be the more frequently invaded; but the disease is generally multiple. The morbid growth more often presents itself upon either of the surfaces of the heart, rather than in its substance. Encephaloid is the most common; epithelioma by far the most rare. The extent of cardiac wall involved by the growth is sometimes great. When the nodules project externally, they are associated with pericarditis, either local or general. Similarly, prominent nodules in the interior of the heart may cause local endocarditis and thrombosis; in other instances the valvular structures are so involved that incompetence results. In very rare cases the degeneration and softening of the new tissue may lead to rupture of the heart.

SYMPTOMS.—In the great majority of cases of malignant disease of the heart no symptoms are present. Very rarely the subject of the disease suffers from severe præcordial pain, possibly anginal, dyspnoea, palpitation, and vomiting; and death may occur suddenly. In cancer of the heart spreading from the mediastinum or lungs, dyspnoea, cough, and pain are necessarily frequent symptoms. Tenderness on percussion over the præcordia (in association with local pain), pericardial friction, and endocardial murmurs due to involvement of the valvular

apparatus in the new-growth are the only physical signs that have been specially observed.

The disease naturally ends in death, perhaps suddenly.

Malignant disease of the heart has probably never been diagnosed. The appearance of true cardiac pain, or of any of the physical signs just mentioned, in the course of a case of cancer, would suggest that the heart might be involved secondarily.

TREATMENT.—The treatment of malignant disease of the heart is limited to the relief of distress.

Non-Malignant Tumours.—These are among the very rarest of morbid appearances in connection with the heart. *Myxomata* have been recorded as instances of this class of diseases. *Lipomata*, *myxomata*, and *fibromata* have been described.

Cysts.—The occurrence of true cysts in the myocardium (hydatids, abscesses, hæmatomata, and softening gummatous being excluded) is doubtful.

Actinomycosis is very rare, and may simulate malignant tumours. It is generally secondary to primary infection of the lung.

J. MITCHELL BRUCE.

HEART, Palpitation of.—**SYNON.** : Fr. *Palpitation du Cœur*; Ger. *Herzklopfen*.

DEFINITION.—Abnormal movement of the heart, without appreciable structural lesion; the movement, frequent or tumultuous, varying in tone and force. See HEART, Functional Disorders of.

HEART, Passive Congestion of.—The coronary veins, like the veins of other parts, are subject to engorgement when the flow of the blood from them into the right auricle is interrupted. The most common cause of this interruption is dilatation with distension of the cavities of the right side of the heart, which conditions are themselves usually due either to emphysema or to valvular disease of the heart. Disease of the trunks of the coronary veins and pressure upon them may be regarded as less frequent causes of cardiac congestion.

Post mortem, congestion of the heart is recognised, when recent, by fulness of the veins on the surface of the organ; by œdema of the loose connective tissue at the base; and by ecchymosis of the pericardium and endocardium. The pericardial sac contains some serous or sero-sanguinolent effusion; and the mouth of the coronary sinus may be found to be dilated. When the congestion is slight, gradually developed, and of long standing, the venous fulness gives rise to an increased formation of connective tissue in the walls of the heart, which become, in consequence, tough and indurated; while the dilatation of the cavities, with which the congestion is associated, is rendered permanent by the same cause. When divided with the knife, the cardiac walls do not fall inwards; their substance feels like a piece of leather; and the section has a smooth homogeneous appearance. Microscopically, the connective tissue seems to be increased in quantity; and the muscular fibres are in a condition of granular, fatty, and pigmentary degeneration.

Congestion of the heart should never be overlooked in estimating the effects on the circulation of passive congestion, which must impair the functional activity of the heart in the same way as it impairs that of the liver, stomach, and kidneys.

J. MITCHELL BRUCE.

HEART, Rupture of.—The heart is liable to rupture from external injuries, and from causes acting from within. The latter are called spontaneous ruptures, and these only will be considered here.

ÆTIOLOGY.—Intrinsic rupture of the heart may be said never to occur spontaneously when the walls are healthy. The following are the diseased conditions of the heart's walls that *predispose* to rupture:—Myomalacia cordis; hydatids, new-growths, and hæmorrhage in the walls; abscess, ulceration, and fatty degeneration. Of 100 recorded cases of rupture, Quain found the heart fatty in 77. Of the same 100 cases 63 were over sixty years of age; and of 98 cases 54 were males. The *exciting* cause of rupture of the heart is usually excitement or effort; but it may occur during rest or the ordinary avocations of life.

ANATOMICAL CHARACTERS.—In 76 per cent. of cases the left ventricle was the *seat* of the rupture; in 43 per cent. the anterior wall; the right ventricle was ruptured in 13 per cent.; the right auricle in 7 per cent.; the left auricle in 2 per cent.; the septum in 4 per cent.

In rupture of the heart the torn part presents various characters. In *complete* rupture the opening may hardly admit a probe, or it may be several inches in length; it may be longer externally or internally; single or multiple. In *incomplete* rupture the injury may be confined to the internal surface, or to the external surface, or it may occur in the substance of the walls. The edges of the rent are ragged, irregular, from tearing or splitting of the muscular fibres, and sometimes ecchymosed; or the parts may appear ulcerated or perforated. The pericardium generally contains blood-clot and serum.

MECHANISM.—When the walls of the heart are softened by degeneration, or are very thin, as is sometimes the case in the auricles or the right ventricle, they may give way before the pressure to which they are exposed during muscular efforts or strains, or even in the ordinary action of the organ. A part of the wall of the heart is then torn across by the contraction of the healthy fibres among which the tear occurs. Or again, when the walls of the heart are thick, it may be that the outer surface, being strained over the contents of a distended ventricle, as would be the outer surface of an overbent hoop, gives way, tears, and the opening gradually extends from without inwards. Thus rupture is more frequent in the left than in the right ventricle, and its explanation is to be found in the fact that it is also more frequently the seat of fatty degeneration. Further, if hæmorrhage takes place into a softened spot in the substance of the heart, the hæmorrhagic area may yield either externally or internally, and give rise to rupture.

SYMPTOMS.—The symptoms of rupture of the heart may be described as (1) premonitory, and (2) immediate. The former indicate a diseased condition of the organ—breathlessness on exertion, palpitation, more or less irregularity of pulse and faintness. These symptoms may be so slight as hardly to attract attention; or so severe as to cause intense suffering. In the majority of cases no mention is made of preceding symptoms, and death is sudden.

The occurrence of the lesion itself, when the patient lives long enough to describe his sensations, is always marked by intense præcordial pain, distress in breathing, restlessness, rapid and irregular pulse, faintness, pallor, coldness of the skin, sometimes vomiting, and loss of consciousness and convulsions.

If life be prolonged beyond a few minutes, there may be slight intermission in the progress of these symptoms. The duration of the attack itself varies remarkably. In 71 out of 100 cases, death occurred within one or two minutes. One patient, however, lived eight days, 1 six days, 1 three days, 5 two days, 3 nearly twenty-four hours, and 19 various times between five minutes and twelve hours.

The *physical signs*, so far as they can be ascertained, are diminished impulse; muffled, distant, or imperfectly developed sounds; and a weak and intermittent pulse.

COURSE AND TERMINATIONS.—The progress of the fatal malady depends much upon the seat of the rupture, the size of the opening, and the rapidity with which the extension of the laceration takes place. When the septum is torn, there is no external hæmorrhage, and life is prolonged until the patient dies from disturbance in the functions of such an important organ as the heart. The progress of the symptoms is also influenced by the direction and course of the rupture. If the torn fibres overlap from the inside or from the outside, the injury penetrates slowly through the cardiac wall, and the fatal progress is also slow.

PROGNOSIS.—As far as is known, rupture of the heart is always fatal. Still it is possible that such an accident, owing to the small size of the opening, its incomplete character, and its occlusion by a coagulum, might not end in death.

TREATMENT.—Little can be done in the way of treatment of rupture of the heart. The patient's sufferings must be relieved by a hypodermic injection of morphine, or by the use of sedatives or antispasmodics. Perfect rest should be maintained if possible.

RICHARD QUAIN.

J. MITCHELL BRUCE.

HEART, Syphilis of.—Syphilitic disease of the walls of the heart is comparatively rare. The congenital as well as the acquired form of the disease has been met with.

ANATOMICAL CHARACTERS.—This morbid condition presents two leading forms. *Gummata* of the heart appear as pale yellow patches in the cardiac wall, or are found on section as yellowish nodules. They present a variety of appearances, according to their age. When young, they are firm or even fibrous, elastic and homogeneous; creak on section; and are very slightly succulent: when older, they become soft and cheesy. In either form the masses are not isolated, but pass continuously into the myocardium, either directly or through the medium of soft vascular connective tissue, so that they were originally described in this country as 'infiltrations' or 'fibrinous deposits.' The superjacent endocardium or pericardium is vascularised and dull in the early stage of the nodules; opaque and thickened in the more advanced stage. The masses or nodules occur in various numbers in different instances, but are generally multiple. They may be found in any part of the heart. Gummata most frequently become caseous in the centre, as described; and they may then soften more completely and discharge inwards, leading to acute cardiac aneurysm and ulcer of the wall; but more frequently the cheesy products are in a great measure absorbed, leaving a puckered fibroid patch behind.

The second form of syphilitic disease of the myocardium is the *fibroid patch*. This is sometimes

well-defined and localised, and in such instances it represents the stage of full development of an area of ordinary syphilitic interstitial inflammation. In other specimens the fibroid patches appear as irregular masses of indurated fibrous tissue, occupying part of the wall of the heart, and sending septa into the depth of the myocardium, while the endocardium and pericardium that correspond to them are opaque, thickened, and puckered. The syphilitic nature of such patches may be determined by the presence of specific lesions in other viscera; and doubtless they may originate in incomplete local or temporary invasion of the coronary branches by syphilitic arteritis.

An intermediate form of the disease is one in which the outer zone of the gumma has undergone development into fibrous tissue, and the caseous centre remains.

The microscopical characters of syphilitic growths do not require to be described here. In the heart, the primary seat of the disease is the intermuscular tissue. The muscular fibres lying imbedded in the gummatous products or in the fibroid growth are either healthy in appearance, or fattily degenerated and broken up.

Syphilitic endarteritis also affects the coronary vessels or their branches, and may give rise to infarction of the walls of the heart, softening, or fibrosis as described above.

Among the occasional effects of syphilitic disease of the myocardium are chronic aneurysm of the walls; distortion of the orifices and of the valves and their appendages; and, more frequently, adhesion of the pericardial surfaces. Some of the other viscera present, as a rule, evidence of syphilis.

SYMPTOMS.—The subjects of syphilis of the walls of the heart may, from a clinical point of view, be divided into three classes. The first class of patients suffer from some one or other of the ordinary symptoms of chronic cardiac disease, such as dyspnoea, cardiac distress, palpitation, pulmonary complications, and general dropsy; while the physical signs are those of cardiac enlargement, and possibly of valvular incompetence. Præcordial uneasiness, syncope attacks, and remarkable infrequency of the pulse have been prominent features in several recorded cases.

The second class of subjects of this disease die suddenly, after few if any complaints referable to the heart.

The third class die of syphilitic marasmus, and may or may not present some evidence—by physical signs or otherwise—that the heart is not sound.

In many of the cases other symptoms of visceral syphilis have been prominent, for example, phenomena connected with the nervous system.

DIAGNOSIS.—Well-defined symptoms and physical signs connected with the heart, particularly those just mentioned, occurring in a syphilitic subject at a comparatively early age for degenerative lesions, would furnish considerable grounds for the diagnosis of specific cardiac disease, in the absence of other more probable causes—such as a history of endocarditis, strain, or Bright's disease. Success of specific treatment supports the diagnosis.

PROGNOSIS.—If such a diagnosis were positively made, the prognosis would be by no means favourable in spite of the hope that the condition might be successfully controlled by specific treatment, the coronary arteries being frequently involved and the nutrition of the myocardium seriously threatened.

The liability to sudden death must not be overlooked.

TREATMENT.—Anti-syphilitic remedies, especially potassium iodide, should be freely tried, along with other cardiac measures indicated on general principles. See also HEART, Valves and Orifices of, Diseases of.

J. MITCHELL BRUCE.

HEART, Thrombosis of.—**SYNON.**: Heart-clotting; *Fr. Thrombose Cardiaque*; *Ger. Gerinnungen im Herzen*; *Herzpolypen*.

DEFINITION.—Coagulation of the blood within the cavities of the heart during life.

ÆTIOLOGY.—Thrombosis of the heart is principally determined by local arrest of the movements of the blood within its cavities. The peculiar saccular condition of the extremities of the auricular appendages, and the trabecular arrangement of the columnæ carneæ of the ventricles, as well as the distance of the same parts from the main blood-currents, determine the favourite localisation of the thrombosis. Roughening of the endocardium and the presence of micro-organisms are also causes of cardiac thrombosis, which might be considered less common than those already mentioned, unless vegetations, the fibrinous coagula of endocarditis, be regarded as thrombi, which, in the strict sense of the term, they are. Certain conditions of the blood contribute to the occurrence of cardiac thrombosis. Finally, thrombi once formed tend to promote the further progress of the condition. See THROMBOSIS.

ANATOMICAL CHARACTERS.—Coagula found within the heart are of two kinds, which have been termed *active* and *passive*, according as they are formed during life, or at or after death, respectively; and the characters of the former, with which alone we are here concerned, cannot be understood until those of the latter have been briefly described.

Passive coagula are found in the heart in most necropsies, occupying the track of the principal blood-currents. Frequently they appear as black or red blood-clots, occupying the auricles principally, and moulded in their cavities. In other cases they take the form of masses of firm whitish fibrin, cleaving with some tenacity to the endocardium, but not truly adherent; matted with the chordæ tendinæ and columnæ carneæ; and projecting some distance into the pulmonary artery. Or, again, passive coagula may be a combination of the two previous forms, the upper part (according to the position of the body) being decolourised or fibrinous, the deeper part resembling more an ordinary blood-clot. In certain cases these passive clots are peculiar. In phthisis and other diseases proving fatal by very slow exhaustion, they are remarkably firm and fibrinous, and closely matted among the chordæ tendinæ—appearances which seem to indicate that coagulation was slowly proceeding for some time before the heart finally ceased to beat. In anæmia they are jelly-like and translucent. In leuchæmia they are soft and creamy in appearance, and yield, when broken up, a puriform fluid. In the acute exanthemata these passive clots are soft and friable; and in many cases of these and of other forms of acute disease and of sudden death, no coagula are found in the heart, which contains only fluid blood.

Active coagula—the result of thrombosis of the heart—are, on the contrary, situated in the saccular appendages of the auricles, at the apices of the ventricles, and in the recesses behind and between

the columnæ carneæ—in other words, as far as possible from the track of active blood-currents. In these situations they may be seen projecting in the form of fleshy knobs or globes, with their free surface smooth and rounded. Their deep surface is adherent to the endocardium, from which, however, it can generally be separated without much difficulty, leaving behind it a discoloured mark. If the thrombus be incised, it will be found to be laminated in structure, somewhat after the fashion of an onion, the colour of the section being greyish-brown or yellowish, with irregular patches of red and black. In most instances the centre is less firm than the periphery; it usually consists of a sanious puriform fluid.

If the process of thrombosis have been proceeding for some time, these formations may extend in all directions, embrace the columnæ carneæ, coalesce in front of them, and finally may fill up a considerable portion of one, or even of more than one, cavity. The thrombi are generally friable; but sometimes they gain in firmness by the deposit of lime-salts within them; and at other times it is possible that they become detached and form into the 'fibrinous balls' which have been found lying free in the cavities of the auricles. Cardiac thrombi may, in part at least, be reabsorbed. They frequently give way during life; and portions of them, as well as of their puriform contents, are conveyed into the circulation, causing embolism and pyæmia.

SYMPTOMS.—The clinical phenomena associated with cardiac thrombosis may be described as those of the last stage of chronic disease of the heart. Præcordial distress and restlessness; irregularity and feebleness of the pulse; œdema and coldness of the extremities; pulmonary congestion, infarction and œdema; dulness of expression, and sopor, broken by low weak delirium; with other symptoms, as well as with the signs of cardiac failure and insufficient emptying of the cavities in systole—all these phenomena are associated with the process of active coagulation within the heart. These phenomena are not directly referable to the thrombosis. All that can be said is, that in such a case thrombosis is probably going on and increasing the embarrassment and the gravity of the condition. An unusual degree of progressive cyanosis appears in some instances. The symptoms of arterial embolism may suddenly make their appearance from detachment of particles of the clots; and, if the puriform contents find their way into the circulation, septicæmia may result.

Cardiac embolism.—The dislodgment *en masse* of a large venous thrombus, and the impaction of the same, or of a 'fibrinous ball,' in one of the orifices of the heart have frequently caused rapid death. See PULMONARY VESSELS, Diseases of.

DIAGNOSIS.—In the presence of the very serious conditions with which cardiac thrombosis is usually associated, the question of its existence is not a point of great importance.

TREATMENT.—The treatment of cardiac thrombosis consists in the treatment of its cause; and nothing is demanded or can be done for the former which is not indicated for the relief of the latter.

The treatment of *embolism* of the pulmonary artery is described separately.

J. MITCHELL BRUCE.

HEART, Tuberculosis of.—Independently of the pericardium, the heart itself is believed to be

rarely the seat of tuberculosis. Grey miliary tubercles have been found in the connective tissue of the wall of the heart in acute general tuberculosis. Tubercle-bacilli occasionally occur on endocardial ulcers. In other instances the 'tubercle' has been of the yellow or cheesy kind, in the form of small nodules lying at various depths in the muscular tissue beneath the pericardium; the latter also being frequently affected, as well as the lungs, intestines, and other organs.

There appears to be no evidence that tuberculosis of the myocardium gives rise to definite symptoms, or that it can be recognised during life.

J. MITCHELL BRUCE.

HEART, Valves of, Aneurysm of.—**DEFINITION.**—A valvular aneurysm is a circumscribed pouching or sacculation of one of the valve-segments.

DESCRIPTION.—Two forms of aneurysm of the valves of the heart are met with. In the one, the whole thickness of the valve is dilated by the blood-pressure so as to form a pouch; in the other, one of the lamellæ being ulcerated by endocarditis, the blood pushes the remaining lamella before it to form a sac. The second form, which is sometimes called 'acute valvular aneurysm,' occurs most commonly in ulcerative endocarditis. Valvular aneurysms vary in size from a pea up to a pigeon's egg. The orifice is almost invariably towards the side of greatest blood-pressure—those on the mitral valve opening towards the left ventricle, those on the aortic valves towards the aorta. They are usually rounded in shape, but may have irregular prolongations between the lamellæ of the valves. Valvular aneurysms are sometimes multiple. The valves of the right side of the heart are seldom affected. The mitral valves are the seat of the larger aneurysms, and are twice as often aneurysmal as the aortic valves.

Valvular aneurysms terminate commonly by early rupture, giving rise to perforation and consequent insufficiency of the valve, and often leading to considerable laceration. Rupture occurs more rapidly in aneurysm of the aortic valves. Mitral aneurysms occasionally become chronic, and filled with solid blood-clot; and aneurysms of the aortic valves may more rarely be found in this condition.

SYMPTOMS.—When seated on the mitral valve, aneurysms usually give rise to no signs until the perforation and laceration of the valve suddenly develop the murmur of mitral insufficiency. An aneurysm of one of the aortic segments may cause a soft systolic murmur over the valves, which one day, as the sac ruptures, is supplemented by a diastolic murmur, and accompanied by the symptoms of aortic regurgitation. The phenomena of this accident are similar to those of sudden rupture of an aortic valve.

B. WALTER FOSTER.

HEART, Valves and Orifices of, Diseases of.—**CLASSIFICATION.**—Two different forms of disorder of the circulation—obstruction and regurgitation—may result mechanically from disease of the valves and orifices of the heart. Valvular disease, on the one hand, is said to be *obstructive* when narrowing of an orifice (*stenosis*) presents an obstacle to the passage of the blood-current. On the other hand, when the blood regurgitates or flows back through an orifice, in consequence of imperfect closure (*insufficiency*) of the valves, due either to

valvular changes or to widening of the orifice, the condition is called *regurgitation*.

Aneurysm of the valves of the heart is discussed separately. See HEART, Valves of, Aneurysm of.

ÆTIOLOGY.—Each of the orifices of the heart may be affected with one or both forms of disease, but the frequency with which they are severally attacked varies. The results of organic disease are chiefly met with in the left side of the heart, and are due to local inflammation (endocarditis) and its consequences, or to chronic degenerative changes, such as atheroma. In adult life the valves of the left side are more frequently affected than those of the right, because they have to bear a much greater pressure; but in fetal life, when the pressure is reversed, the right valves suffer more. Endocarditis is commonly of rheumatic origin, and attacks the mitral more frequently than the aortic valves; the former having to sustain the full force of the ventricular systole, while the latter only bear the force of the aortic recoil. In addition to rheumatic fever, the chief diseases which tend to develop endocarditis are pyæmia, septicæmia, and the acute infective fevers. Valvular disease may be met with in chorea, but in this connection is probably of rheumatic origin. Gonorrhœal infection is occasionally followed by endocarditis. The aortic valves and orifice are more commonly affected than the mitral by chronic endarteritis extending from the aorta, the chief causes of which are gout, old age, syphilis, chronic renal disease, strain, and the abuse of alcohol. These facts explain why mitral affections (commonly rheumatic) occur mostly in early life, and aortic affections in later life. Valvular lesions are more common in men than in women, owing to their more laborious occupations. Direct rupture of a valve owing to a sudden strain may occur. This is most frequently met with in the aortic valves, but similar accidents may occur to the mitral valve and its tendinous cords. Valvular defects are also due in some cases to congenital malformations. See HEART, MALFORMATIONS OF.

ANATOMICAL CHARACTERS.—The pathological changes in the valves and orifices of the heart, which cause valvular defects, are mostly the results of acute or chronic endocarditis. In the acute form, the valvular lesion is caused by the growth of vegetations which interfere with the action of the valve-segments; or by softening and ulceration of the valve-structure, which lead to valvular aneurysm and perforation, or to loss of substance and consequent insufficiency. The more chronic forms of inflammation produce thickening of the valves from overgrowth of the connective tissue, with subsequent retraction from shrinking of the newly formed fibrous elements; or adhesion of the valve-segments causing stenosis.

Aortic stenosis, when not due to congenital malformation, is generally the result of thickening and calcareous degeneration of the valves, or of deformity of the valves from vegetative growths which obstruct the free passage of the blood from the ventricle. Sometimes it is due to adhesion of the valves preventing their elevation, and causing them to form a diaphragm with a narrow central aperture. More rarely it is caused by thickening and contraction of the fibrous ring of the aortic orifice, gradually involving the valves; or by endocardial thickening producing contraction immediately beneath the aortic ring.

Mitral stenosis results most frequently from

thickening and rigidity of the valves, which contract all round the mitral orifice, so as to narrow the outlet, and form a diaphragm between the auricle and the ventricle. This diaphragm is in some cases funnel-shaped, while in others the mitral orifice is transformed into a button-hole aperture, or narrowed to the size of a goose-quill. The tendinous cords of the valve are shortened, and their muscles thickened. In some cases the valves are smooth and thin; in others they are thickened, studded with vegetations, rough and calcareous. This latter state may cause stenosis, without any funnel-formation, as may also fibrinous clots or polypii obstructing the orifice. In many cases of mitral stenosis the valves are also insufficient. Mitral stenosis is mostly observed in young females, as a result of mild rheumatic attacks or chorea. It is sometimes called congenital in cases in which it can be referred to no acute illness.

Aortic insufficiency sometimes depends on dilatation of the aortic orifice, due to softening of the aortic coats, with little or no change in the valves, which are incapable of closing the enlarged orifice. This may be called *relative* insufficiency. Vegetations, thickening, retraction, calcareous degeneration, adhesions, perforations, loss of substance, and rupture of the valve-segments by effort are all causes of aortic insufficiency. In rupture of the valves, a full description of which was first given by Sir Richard Quain (*Edin. Monthly Journ.* 1846), the valve-segment is torn from its angle of attachment, and its free edge retroverted towards the ventricle. This accident happens most frequently in cases where the valves were previously diseased by chronic inflammatory changes connected with the strain of very laborious occupations, and in such cases further laceration may subsequently occur.

Mitral insufficiency is due to thickening, retraction, or deformity from vegetations, of the valve-curtains; adhesion of the curtains to each other or to the ventricular wall; and calcareous degeneration. In some instances one of the valves is perforated or torn; and sometimes the tendinous cords are shortened and thickened, or ruptured as the result of degeneration, preventing the normal action of the valve-curtains. In rarer cases associated with dilated ventricle, the papillary muscles are so weakened by degeneration that they can no longer aid in the closure of the orifice. Dilatation of the left auriculo-ventricular orifice is also a cause of *relative* mitral insufficiency. This form is unconnected with structural valve-changes, and is due to defective muscular contraction, such as occurs in anæmia, typhoid fever, and the failing systole of the later stages of aortic insufficiency.

Valvular defects on the right side of the heart are due to similar changes. They arise chiefly during fetal life, when the right cavities have to bear greater pressure. In adult life these defects are generally associated with diseases of the lungs, which cause increased tension in the right cavities, and lead to their dilatation.

Combined valvular lesions are not infrequent. The most common are stenosis and insufficiency of the aortic valves, along with the same morbid changes of the mitral valves. Endocarditis of the mitral orifice may spread directly to the aortic valves by way of the intervening surface of endocardium. In the last stages of both forms of aortic valvulodisease, the mitral valve becomes insufficient, either from chronic endocarditis, or from dilatation of the

ventricle and of the auriculo-ventricular orifice. Mitral stenosis is not infrequently associated with aortic insufficiency, but is more commonly connected with some degree of narrowing at the aortic orifice. Tricuspid insufficiency is usually met with in the last stages of diseases of the left heart and of some forms of pulmonary affection; and tricuspid stenosis as a congenital malformation is met with in connection with a similar narrowing of the mitral orifice.

EFFECTS.—Valvular diseases of the heart produce a series of morbid phenomena, which are connected together by a necessary sequence. Each and every form of valvular defect impairs the perfection of the heart as a pumping machine, and disturbs the normal relations between the contents of the arteries and of the veins. In front of the lesion there is less blood; behind it there is more. In aortic valvular diseases, the first effects are increase of the blood-pressure in the left ventricle, and lessened blood-pressure in the aorta; next, from the difficulty which the left auricle has in emptying all its contents into an over-full ventricle, there is produced increased pressure in the left auricle and pulmonary veins. Lesions of the mitral valve cause similar results: first, increased pressure in the left auricle, less pressure in the left ventricle, and consequently lessened pressure in the aorta, with a gradual increase of pressure extending from the left auricle to the pulmonary veins. Aortic affections thus act first on the arterial, and secondly on the pulmonary circulation; while mitral lesions affect the pulmonary vessels more immediately. The final results of the two forms are, however, identical, and may be stated in the form of a law—namely, that *all valvular diseases of the heart tend to lessen the quantity of blood in the arterial system, and to produce increased fulness and stasis in the veins*. From the action of this law, various associated visceral disorders follow as consequences. These disorders, however, vary greatly in the period of their occurrence, and in the intensity of their manifestations. This variation is due to the more or less perfect way in which the original valvular defect has been compensated for, by changes in the power of the cardiac muscle and in the capacity of the cardiac cavities. These changes often suffice to maintain fairly the normal balance between the arterial and venous contents, thus *compensating* for the valve lesion; and the process by which this is effected demands careful consideration.

Compensation.—Compensation is effected differently, according to the form of disease. It may be stated generally, that it consists in hypertrophy of the cavity immediately behind the defect. Now hypertrophy means increased contractile power, and consequently better filling of the arteries, and increased arterial tension. Thus it makes up for the valvular incompetency, which tends to lessen arterial tension. When the increased power of the ventricle exactly balances the effects of the valvular mischief, the compensation is complete.

In *aortic stenosis*, hypertrophy of the left ventricle is the mode in which compensation is effected; the obstacle to the blood-current is overcome by the increased muscular power.

In *aortic insufficiency* there is some dilatation of the ventricle as the primary result of the lesion, accompanied by hypertrophy of the muscular wall. A sufficient excess of blood is thrown into the aorta at each systole to allow for the regurgitation during

each diastole; and thus the balance is maintained, though not always equally.

In *mitral lesions* the left auricle is dilated as the primary consequence of the condition of the valves; hypertrophy follows, but is generally insufficient to prevent increased fulness of the pulmonary veins. This impedes the circulation in the lungs; and increased tension in the pulmonary artery soon begets the necessary hypertrophy of the right ventricle. It is by means of this increased power of the right ventricle that the blood is driven through the lungs in spite of the defect in the left heart, and pulmonary stasis is prevented; and the blood entering the left auricle under greater *vis à tergo*, the compensation of the valvular defect is effected. The compensation, from the nature of the means on which it depends, is manifestly less perfect than in aortic lesions.

On the *right side of the heart* similar modes of compensation are observed.

The basis of the salutary changes just described is increased cardiac nutrition; and, consequently, a free coronary circulation is a necessity. Conditions which interfere with this prevent compensation, and so diminish the duration of life. Of the causes of failure of compensation in cases in which this condition has once been established, the most important is over-exertion, causing strain upon the heart. Affections of the lungs such as bronchitis, by throwing extra work upon the right ventricle, may have a similar effect. Acute diseases or starvation, by interfering with the general nutrition, may also cause a damaged heart to fail. Wherever the compensation begins to fail, dilatation of the cavities and vessels behind the lesion commences. This may, however, be checked, and the power of the heart restored for a time. Sooner or later, however, changes in the nutrition of the cardiac muscle, in the vessels, and in the general nutrition, bring on failure of compensation. The cardinal symptom in such cases is weakened contractile power of the heart (*asthénie*, Beau). In this state, the cavity chiefly affected has no longer power to expel its contents fully into the vessels, and consequently becomes gradually and increasingly distended. Failing compensation in aortic valve-disease manifests itself by dilatation of the left ventricle, and the development of secondary mitral insufficiency. Similar retro-dilatation marks the failure in mitral cases, only here it is the right ventricle which dilates, and tricuspid insufficiency and general venous stasis are added to the pre-existing pulmonary engorgement.

Visceral complications.—The most important of the associated disorders of chronic valvular disease, depending on defective contraction of the heart, are the visceral congestions.

In the *lungs*, the habitual engorgement of mitral disease produces a hyper-secretion of mucus and a state of chronic catarrh. The blood-vessels also undergo changes from the excessive intravascular pressure, and become dilated, varicose, and atheromatous; hence oedema and hæmorrhage arise. In mitral stenosis especially, grave and frequent attacks of hæmorrhage, with laceration of the pulmonary substance, are liable to occur, as well as other chronic changes. See LUNGS, Hyperæmia of; Brown Induration of; and Hæmorrhage into.

In the *liver*, venous stasis results from the obstruction to the passage of blood from the hepatic veins into the inferior vena cava. Passive congestion ensues, and 'nutmeg liver' results (see LIVER,

NUTMEG). The passive congestion in the liver, as in the lung, causes catarrh of the tubes, and may thus be productive of slight jaundice. Among other symptoms associated with the hepatic congestion may be mentioned hæmorrhoids and epistaxis.

The *spleen* is a very easily distended organ, and suffers like the liver, but frequently before it; and this may partly account for the pain in the early stages, which is complained of beneath the left ribs. In long-standing cases the spleen becomes tougher, and the capsule opaque and thickened; while hæmorrhagic infarcts are common.

From the hepatic congestion there naturally follows distension of all the other radicles of the portal vein; hence the congestion and chronic catarrh of the *stomach* and *intestines*, which impede digestion and assimilation, and so reinforce the other causes producing the cachexia of chronic valvular disease.

The function of the *kidneys* is more or less disordered. The first stage of general circulatory trouble is lessened arterial tension; this makes itself felt in lessened pressure in the Malpighian tufts, and is manifested by scanty, dense, high-coloured urine. Later on the venous stasis in the kidney leads to the transudation of serum, and consequently albumen appears in the urine. Long-continued venous congestion ends in structural changes, which, as elsewhere, consist in connective-tissue hyperplasia and degenerative (rarely fatty) changes in the tubules. These renal changes sometimes add uræmia to the patient's ailments.

In the *brain* decided alterations are not found, except when a detached vegetation produces embolism and its special phenomena. The brain-substance is, however, generally oedematous, and the membranes are thickened. Delirium is an occasional symptom in heart-disease, and when present to any great degree is of evil import. The blood-vessels of the general circulation are frequently affected with atheroma in hypertrophy of the left ventricle, and it is these degenerative changes, as well as embolic aneurysm, which favour the occurrence of apoplexy.

General dropsy.—The mechanical impediments to the circulation which produce these several visceral congestions, also manifest themselves in the general dropsy which is common in the last stages of heart-disease. The dropsy begins as a puffiness of the ankles, especially the left, at bedtime. The general venous stasis, thus first indicated, advances slowly and surely, if not checked, to general anasarca, and even to dropsy of the serous cavities. The increased venous tension, and the hydræmia of blood-deterioration, are the causes of this serous transudation, which shows itself first in the feet, the most dependent portions of the body, where the pressure of the blood-column is naturally greatest. The horizontal posture, by distributing the pressure, is sufficient at first to disperse the oedema of the ankles. General anasarca is much more frequent in mitral disease, especially the regurgitant form, than in aortic lesions.

In some cases a solid form of oedema is observed. This occurs mostly in the last stages of valvular affections, and is due to thrombosis of venous trunks, in which, the circulation being much impeded, coagulation easily takes place. The termination of the external jugular veins is a common site for such thrombosis; and the left innominate vein, from its transverse position, and from its emptying into the superior vena cava, almost at right angles to the current, is, in the writer's experience, more com-

monly obstructed than the right. Solid oedema is consequently seen more frequently on the left side of the head and neck and in the left arm, than on the right side.

SYMPTOMS.—The earliest symptoms of failing compensation are breathlessness and palpitation on slight exertion, and in mitral cases frequently the appearance of slight oedema about the feet and ankles.

Palpitation is intimately related to the state of cardiac nutrition and innervation, and has no special connection with any form of valvular disease. Cardiac pain, varying in intensity from mere uneasiness to the agony of angina, is most common in aortic cases, and is associated with endarteritis, particularly at the root of the aorta, or with dilatation of the left ventricle, or is a neuralgia of the cardiac plexus. In mitral affections, pain arises from over-distension of the left auricle, and its pressure on neighbouring parts, and later on from dilatation of the right ventricle. Dyspnœa may be present in any form of valvular disease, but it is often absent from the earlier history of aortic cases, while some dyspnœa is always present with mitral lesions. This difference is due to the absence of pulmonary congestion in aortic disease, while it is more or less present from the first in mitral affections. The dyspnœa is a breathlessness rather than a difficulty of breathing. It is panting and gasping in its character, with acceleration of the rate. It is aggravated by any movement, and often compels the patient to sit upright (orthopnœa). Headache, vertigo, night-terrors, and sleeplessness are other symptoms, which depend on disordered cerebral circulation. Sleeplessness is one of the most distressing of all symptoms, and can only be relieved when the dyspnœa is lessened. Other more special symptoms will be found in certain cases, and will be traceable to the disturbances in the circulation, which the particular form of valvular disease has engendered.

Physical signs.—The physical signs associated with valvular affections may be said to be—firstly, those of alteration in the size of the heart; and, secondly, those of mechanical disorders of the circulation; together with one or more endocardial murmurs. The persistence of a murmur is the cardinal sign, and if the murmur be either diastolic or præ systolic in its rhythm, it is of absolute value. A systolic murmur, especially at the base of the heart, may be associated with anæmia (hæmic murmur), but in such a case there is no cardiac hypertrophy, as indicated by increased cardiac dulness, though there is often nervous over-action of the heart. There is also no accentuation of the pulmonary second sound, inasmuch as there is no extra-fulness of the pulmonary blood-vessels from obstructed circulation. The pulse in anæmia is generally quick, ample, and compressible, but, withal, jerky; while with an organic systolic murmur it is generally slow, rising gradually under the finger, and not very compressible (aortic stenosis), or small, irregular, and unequal (mitral insufficiency). The clinical methods of investigating valvular lesions are mainly inspection, palpation, percussion, and auscultation. The signs of each form of valve-disease are stated below; and on these the special diagnosis rests.

DIAGNOSIS.—In *Aortic stenosis* there is often some prominence of the præcordial region, and a steady forcible impulse is perceived below and to the left of its normal position. A thrill, systolic

in time, may often be felt at the base of the heart. On auscultation, a loud, frequently rough, rasping, sometimes musical, murmur is heard with the first sound at mid-sternum, and also at the second right intercostal space. The murmur, commencing with the first sound, extends to the succeeding second sound, which is often not very distinct. In relative stenosis with a dilated aorta, the murmur is softer, and the second sound sometimes louder than normal. The murmur of aortic stenosis is audible all over the upper part of the thorax, especially on the right side; is conducted along the great vessels to the left vertebral groove, and it may be even to the lower dorsal vertebrae; and is occasionally heard at the apex of the heart. The pulse is regular, slow, retarded by the narrowing of the aortic orifice, and slowly developed under the finger. The sphygmogram (see fig. 1) shows the line of ascent to be oblique or broken, instead of nearly vertical; the summit is generally blunt; and the line of descent

FIG. 1.—Pulse-tracing in Aortic Stenosis.

shows small or no secondary waves, and ill-developed dicrotism. Aortic stenosis when moderate, requiring only hypertrophy of the left ventricle for its compensation, is often very perfectly remedied by this change, and produces little or no disorder of the circulation.

This is also true of cases in which roughness of the valves or vegetations are the cause of even a loud murmur. The amount of hypertrophy of the left ventricle is the surest guide to the gravity of the condition. When the stenosis is very great, epileptiform and syncopal attacks may occur, and lead to sudden death. When the compensation fails, the mitral valve often yields from dilatation of the left ventricle and degeneration of the papillary muscles. Then the pulmonary second sound becomes accentuated; the pulmonary circulation is embarrassed; and dyspnoea, bronchial catarrh, pulmonary hæmorrhage, œdema, and cyanosis supervene.

In *Aortic insufficiency*, inspection discovers a forcible and diffused impulse, the apex-beat being lower than natural, sometimes as low as the seventh intercostal space, and outside the nipple-line. The præcordial region may be bulging from the enlargement of the heart; pulsation may be seen in the upper intercostal spaces at the right edge of the sternum; and a thrill may sometimes be felt there, and occasionally as low down as the heart's apex. The great vessels of the neck pulsate visibly. The area of cardiac dulness is increased in all directions, but mainly vertically. On auscultation, a murmur is heard, replacing and following the second sound, of a blowing or hissing character, rarely rough, and lessening in loudness towards its end. It is usually loudest at mid-sternum and in the second right intercostal space; and it is conducted upwards to the right clavicle, but mainly downwards to the xiphoid cartilage. It is not heard at the back of the chest. It may be conducted to the apex of the heart rather than to the ensiform cartilage; and this occurs, in the writer's opinion, when the posterior or mitral segment of the aortic valves is the incompetent one, as the regurgitant current then falls on the mitral valve, and the murmur is thus conducted to the apex. The second sound may be wholly lost at the base of the heart, being replaced by the murmur; but in some cases it is audible—this being due either to normal closure of

one or two aortic segments, or to the propagated pulmonary second sound. If audible in the carotids, the second sound is aortic, and is of some value as indicating an incomplete defect of the valves. The second sound is often audible at the apex. The first sound at the base is almost always modified, being generally murmurish and often obscured by a systolic murmur, due to slight obstruction from thickening of the valve-segments, or to relative stenosis and the vigour of the ventricular systole. In some cases there is no distinct first sound audible at base or apex; its absence being possibly due to noiseless closure of the mitral valve by the intra-ventricular blood-pressure before the systole occurs. Thus in cases of free regurgitation, both first and second sound may be absent over the left heart; but on listening over the femoral artery with a binaural stethoscope lightly applied, the two sounds of the heart can sometimes be heard. In the majority of cases the insufficiency is no doubt asso-

FIG. 2.—Pulse-tracing in Aortic Insufficiency.

ciated with some stenosis, and the murmur is double—a short rough systolic portion, with a softer, longer, and more hissing diastolic portion. This double murmur might be well called the *up-and-down* murmur of aortic valve-disease: the two descriptive words indicating the length, and, to some extent, the characters of its component parts.

The signs connected with the pulse in aortic insufficiency are very significant. As the pulsations of the aorta are visible to the right of the sternum, so the arteries often beat visibly all over the body, even to the radial, temporal, and dorsal arteries of the foot. The ophthalmoscope has shown the same phenomenon in the central artery of the fundus oculi. This remarkable movement of the arteries is due to two causes—firstly, to the hypertrophy and dilatation of the left ventricle, which throws an excessive quantity of blood into the vessels at each systole; and, secondly, to the sudden collapse of the arteries, due to the aortic regurgitation. The arterial recoil during the ventricular diastole is not opposed, as in health, by the resistance of the perfectly closed aortic valves, and, consequently, the blood-column is not sustained, and the arteries collapse. These 'locomotive' features in the pulse are generally increased by elevating the arm. The pulse is sudden, short, large, regular, rapidly collapsing, and vibratory. The sphygmographic tracing brings out these characters: the line of ascent is vertical and lofty; the summit is sharp and pointed; the line of descent falls rapidly, and is broken by a series of secondary waves due to vibratory conditions, but has an ill-developed dicrotism. The post-dicrotic portion of the tracing falls rapidly, from the absence of a sustained blood-column. The longer and more oblique this portion of the tracing, *cæteris paribus*, the less copious the regurgitation (see fig. 2).

Aortic insufficiency often lasts for many years without producing any obvious disturbance of the systemic and pulmonary circulations; hence the absence of dyspnoea and œdema. The hypertrophy and dilatation of the left ventricle, which form the

compensation, suffice to prevent ill effects. At each systole the dilated ventricle throws sufficient blood into the aorta to allow for the reflux, and to maintain a fair arterial tension. Thus the compensation is perfect. In many cases, however, if the reflux is free, the coronary arteries, which are partly filled by the arterial recoil, are deprived of the full force of the blood-wave, and the nutrition of the heart consequently suffers. This is the great source of failing compensation, and the malnutrition of the cardiac muscle soon leads to dilatation of the ventricle, secondary mitral insufficiency, and atrophy.

When the hypertrophy is excessive (over-compensation), as it is in some cases, there are flushings of the head and face, headache, vertigo, and violent arterial action all over the body.

In *Mitral stenosis* there is rarely any prominence of the præcordial region; and in its earlier stages neither increase of the cardiac dullness, nor alteration in the position of the impulse. The impulse, when regular, is fairly distinct, but it is often very irregular, and is associated with a thrill, which precedes, runs up to, and terminates in the impulse. In advanced cases, the area of cardiac dullness is increased laterally; the impulse is diffused, and may be seen in the epigastrium; this indicates hypertrophy of the right ventricle, which sometimes obscures the left ventricular impulse and gives rise to epigastric and hepatic pulsation. The left auricular systole may occasionally be noticed, if the chest be thin, in the third left intercostal space. The sounds heard on auscultation in this lesion vary. The pathognomonic sign is a murmur preceding the systole, and ending with its commencement. This is best called the *præstolic* murmur (also 'auricular systolic'); and is produced when the contracting auricle forces blood under high pressure through a narrowed orifice into the ventricle. The first portion of the blood passes from the auricle into the ventricle noiselessly; and it is only when a stream of higher tension is forced into it by the true auricular systole that the murmur is developed. The murmur is, therefore, short in most instances, occupying the last part of the diastole; it runs up to the first sound, and ends abruptly in it. The position in which the murmur is best heard in its typical præstolic form is at the apex-beat of the heart or at a point between this and the left border of the sternum. It is strictly localised and not conducted in any direction.

This murmur is soft and puffing, but may be harsh. It commonly fills only the last part of the diastolic period. In some cases, with greater roughening and deformity of the valves, the murmur is longer, rougher, more rolling or grinding, and ends abruptly with the first sound, which is very flapping in tone, and might easily be mistaken for the second sound conducted. The careful observation of the impulse or of the carotid pulse with the finger, while auscultating, is necessary in order to avoid the error. Mitral stenosis develops three murmurs under different conditions of the valves: (1) A short softish puff (sounding like *vool*) immediately preceding the first sound; (2) a short rough grinding murmur (*rrrr*); and (3) a long murmur filling nearly all the diastole, often rough, but varying in tone in some cases. These several murmurs increase in intensity up to, and end abruptly with, the first sound. The soft, hissing, diastolic murmur, occasionally heard at the apex, which lessens in in-

tensity, and ends before the first sound, is a conducted aortic (or pulmonary) murmur.

A special peculiarity of the præstolic murmur is its variability: it is the only organic murmur which disappears and reappears as the cardiac conditions change. For instance, a murmur, inaudible while the patient is at rest, is developed by a little exercise; or, again, an irregular tumultuous action of the heart masks all murmur, which becomes distinct as the heart steadies down under the action of digitalis. In other cases there is no distinct murmur, but only a slightly prolonged and rough or grinding first sound, while the murmur is often lost as the heart-failure advances. In cases of mitral stenosis there is accentuation of the pulmonary second sound, from the greatly increased tension in the lesser circulation; there may also be a doubling or reduplication of the second sound at the base. This reduplication is a sign of great value in cases in which the prolonged or grinding first sound is the only sign. The reduplication of the second sound is due to a want of synchronous closure of the pulmonary and aortic valves, from their altered relative tension. A doubling of the first sound is sometimes noticed, probably due to retarded closure of the mitral valve, from lessened fullness of the left ventricle.

The rhythm of the heart is frequently greatly disordered in mitral stenosis, and also in mitral insufficiency. A few beats occur regularly, or nearly so, and then a series of very small hurried contractions follows, to be again succeeded by stronger and better pulsations. These irregularities are referable to the varying charges of blood on which the ventricle contracts. The over-distended right cavities and the left auricle contract rapidly to expel their contents, but the narrowed mitral orifice does not allow a full charge to pass into the ventricle; the diastole is too short for this purpose; and the wave of contraction passes on to the ventricle from the auricle, producing a series of small ineffective pulse-beats, each representing a small charge sent into the aorta. When the series of ineffective contractions ceases, the next diastole is longer; and the succeeding systole sends, as the sphygmograph shows, a fuller charge into the arteries. During the small irregular beats the præstolic murmur is often indistinguishable, but it is again heard with the succeeding slower and more effective beats. This irregularity in the heart's rhythm, however, is not present in all cases of mitral stenosis. In some

FIG. 3.—Pulse-tracing in Mitral Stenosis.

instances the heart's action and the pulse are regular. The sphygmograph in such cases records a small pulse of low tension, with a little inequality in the volume of the beats; this inequality is often increased by exercise. In other cases the pulse-tracing is small, irregular, and unequal in its pulsations, and marked by true and false intermissions (see fig. 3).

In the earlier stages of mitral stenosis the face may be pale, and the congestive symptoms which mark mitral insufficiency are absent till the later stages. This form of valvular lesion gives rise more

commonly than mitral insufficiency to hæmorrhagic infarction in the lungs; but in other respects the pulmonary and systemic circulations suffer in the same way as described in the other form of mitral disease. The subjects of this defect are often ill-developed and stunted in growth.

In *Mitral insufficiency* inspection discovers some slight prominence of the præcordial region, with increased impulse, the apex often beating to the left of the nipple line. The area of cardiac dulness is augmented mainly in a lateral direction, from the hypertrophy of the right ventricle. On auscultation, a murmur is heard along with or, more often, replacing the first sound, and following it; loudest at the apex; loud along the left edge of the heart; but absent or not so distinct over the right heart and at the base. The murmur is propagated towards the left axilla, and is audible in most cases in the left vertebral groove near to the angle of the scapula. If not audible posteriorly the murmur signifies regurgitation through a narrowed but patent mitral orifice, and may indicate mitral stenosis, in the absence of either a præstolic or diastolic murmur. The mitral systolic murmur associated with dilated left ventricle or enfeebled muscle is not usually heard posteriorly. The murmur is usually loud, blowing, and distinct in its character, keeping the same tone throughout. The true first sound is generally obscured by it, but in some cases may be heard through it, and is then due to the partial closure of the mitral, or to the action of the right auriculo-ventricular valves. The pulmonary second sound is commonly accentuated. The pulmonary first sound has in some cases a murmurish character, probably due to hypertrophy and dilatation of the right ventricle, and relative stenosis of the pulmonary orifice.

The radial pulse in cases of fairly perfect compensation is regular, but quick, small, weak, and easily compressible; and the sphygmograph shows low tension, and an inequality in the size of the pulsations. In cases of less perfect compensation,

FIG. 4.—Pulse-tracing in Mitral Insufficiency.

it becomes irregular and intermittent. In all cases the pulse-beat is weak in comparison with the vigour of the ventricular systole (see fig. 4).

There is no unusual fullness of the superficial veins in the earlier stages of mitral insufficiency. Later, when the right cavities become over-distended, the veins of the neck become full and may even pulsate. This is very distinct when the tricuspid valve gives way. In all cases slight exertion is sufficient to induce dyspnoea; and there is an ever-present tendency to bronchial catarrh, from the congested state of the lungs. When compensation fails, the murmur becomes less distinct; the heart's action is rapid, irregular, and tumultuous; the accentuation of the pulmonary second sound is lost; dyspnoea becomes orthopnoea; and cyanosis, œdema, and hæmorrhagic infarction of the lungs, with general and visceral dropsy, close the case.

Many cases of mitral regurgitation obtain fairly perfect compensation; but the disease, like mitral stenosis, of necessity entails some dyspnoea on exer-

tion, and keeps up constantly an engorged state of the pulmonary vessels.

Valvular affections of the right heart, arising from disease, are uncommon. Those of the *pulmonary valves* are rare; cases are on record, however, of pulmonary stenosis, and a few of pulmonary insufficiency. In the first case the systolic murmur is loud and superficial, and is heard loudest at the third left costal cartilage close to the sternum, and in the second left intercostal space; it is not usually conducted across the sternum, nor upwards to the right clavicle, as is an aortic murmur. A diastolic pulmonary murmur is soft and blowing; and is heard loudest in the same situations, and downwards towards the ensiform cartilage.

The *tricuspid valves* are more frequently affected. Tricuspid insufficiency is indeed a common sequel of disease of the left side of the heart. Structural changes in these valves are, however, rare. Tricuspid insufficiency does not always produce a murmur; when present this is soft and short, and is heard nearer the middle line than a mitral murmur, at the base of the ensiform cartilage. The pulsations of the cervical veins may indicate the lesion when the murmur is absent.

Tricuspid stenosis causes a præstolic murmur, harsh in character, loudest at the base of the ensiform cartilage and towards the left edge of the sternum, not propagated towards the left heart, and not audible at the back of the chest, though faintly conducted along the sternum to the base of the heart. A præstolic thrill may be present. Mitral stenosis has been observed in association with this lesion, and two præstolic murmurs may be made out in such cases.

The physical signs and the diagnosis of *combined valve-lesions* remain to be described. The mitral and aortic valves may each be affected with stenosis and insufficiency, from a single attack of endocarditis, or from one lesion arising as a consequence of the other. The double aortic murmur, already described, indicates the aortic combination; but it must be always remembered that the systolic murmur in these cases may exist with little or no actual stenosis.

In the double form of mitral disease, either defect may exist alone at first, and afterwards be associated with the signs of the second. In some cases the præstolic murmur may fail to be heard, and a systolic murmur may alone be audible; in other cases, there is a prolonged apex-murmur which slightly changes tone; in other cases, again, a short grinding præstolic murmur is followed, occasionally at an interval, by a soft, blowing, systolic one. The combination of aortic with mitral disease may be recognised by the presence of their special murmurs.

PROGNOSIS.—It is very difficult to state general rules of prognosis in valvular affections of the heart, as so much depends on the peculiarities of each case. There are, nevertheless, certain broad rules. As regards origin, rheumatic inflammation is less serious than degenerative change, which occurs later in life, and is necessarily progressive. Accidental rupture is the gravest form of origin. The valve affected is also a prognostic element; but any attempt to arrange cases in order, according to the seat of the valvular defect, must be open to so many exceptions that it must not be too much trusted. Speaking generally, however, aortic regurgitation constitutes the gravest form of lesion owing to the

liability of the patient to the occurrence of sudden death. Pure aortic stenosis with good ventricular hypertrophy is perhaps the least unfavourable form of valvular defect. Mitral regurgitation is also compatible with the attainment of advanced age, but stenosis of this valve is usually progressive, and the outlook in such cases is grave. For purposes of life-insurance the presence of any valvular defect prevents the subject of it from being accounted a 'good life.' It is probable, however, that some adults with compensated mitral regurgitation might safely be accepted at increased rates.

Aortic cases are often free for years from any grave symptoms. The presence of the second sound over the carotids is favourable. The pulse-tracing also affords valuable aid in prognosis, as it gives, by the size of the dicrotic wave and the obliquity of the line of descent, a rough measure of the amount of insufficiency. There is much more risk of sudden death in aortic cases than in mitral.

In mitral lesions the dangers arise from the pulmonary complications; embolism is more common than in aortic affections. Mitral cases can be rescued from asystole more frequently, and die of advanced cardiac cachexia, generally with dropsy. Under favourable conditions of life, requiring little physical exertion and causing no emotional excitement, both forms of mitral disease are compatible with many years of life. When they are conjoined, the prognosis is more unfavourable. In cases of sudden insufficiency, produced by rupture of the valve-curtains or of the tendinous cords, death may occur very rapidly from the disturbance of the circulation.

The whole question of prognosis turns principally on the state of the myocardium. So long as this is sound, compensation may be maintained; the moment degeneration sets in, cardiac failure and all its evil train of symptoms come on. Such failure coming on gradually, without any previous overstrain of the heart, is always most grave. Each successive attack becomes graver, and the visceral congestions which accompany it more stubborn. Albuminuria is a marked index of the gravity of the congestion, and is serious in proportion to the frequency with which it has occurred. In some cases a copious flow of limpid urine is a very grave symptom. Dropsy of the extremities, and more especially of the cavities, is bad, as indicating failure in the peripheral circulation. Next to the cardiac muscle, the state of the peripheral vessels is most important; thus, petechiæ are bad signs; while atheroma and other conditions, such as febrile attacks, add to the danger by interfering with the circulation. The general nutrition of the patient suffering from valvular disease also enters into the prognostic problem. There is a 'cachexia' proper to the end of heart-cases, which is due to the gradual deterioration of the nutritive fluids by the long-continued visceral congestions which hinder assimilation and excretion. Blood is less perfectly made and less perfectly purified; hence the steady deterioration of the general condition, which is always of evil import as regards duration of life. In the poor, the prognosis, as to duration, is not favourable owing to the difficulty of obtaining the needful amount of rest and of nourishing food; but in the well-to-do, all observers see many cases extending over a great number of years.

TREATMENT.—Valvular affections of the heart, whether the result of rheumatic inflammation or of

degenerative change, are, as a rule, incurable. Some few cases of rheumatic origin lose the signs of valvular disease, and are practically restored by the after-processes (for example, contraction) in the inflamed valve; and some few cases also of mitral insufficiency, associated with dilated left ventricle and softened muscle, are cured by treatment. These exceptions are, however, few; and as we cannot repair the valve-mischief, in the vast majority of cases our treatment must be directed to aid the compensatory hypertrophy, and to check the development of the consequences of the defect. The maintenance of the nutrition of the substance of the heart is, therefore, the main object of treatment; just as the state of the nutrition of the heart is the key to the prognosis. On this account the general regimen of heart-cases is very important. In cases in which good compensation is present, no treatment directed to the cardiac condition alone is necessary.

Prophylaxis.—Since valvular disease is generally the result of rheumatism occurring in childhood, it is important to watch carefully for indications of this disease and to treat it effectually. Slight pains in the limbs—frequently muscular—should not be neglected: such so-called 'growing pains' necessitate a careful examination of the heart, and if the slightest murmur be detected complete rest in bed should be insisted upon. Salicylate of sodium should be given in all cases of rheumatic pains in children. See RHEUMATISM.

General regimen.—The diet should in all cases of valvular disease of the heart be unstimulating but sustaining, consisting of a good proportion of albuminous food (meat, eggs, poultry, and fish), with wine in moderate quantity, and some chalybeate water. There should be no unnecessary excitement of the heart, either by exercise or emotion. All athletics and violent efforts should be avoided. In boys, football and all forms of racing must be forbidden. Cricket and gentler outdoor games may be permitted in well-compensated cases, and gentle horse-exercise is often beneficial. Bicycling upon level ground is admissible, but up-hill this form of exercise is carefully to be avoided. In aortic cases, steady exercise without strain is beneficial. The residence should be so situated as to avoid the necessity of exertion, sudden changes of temperature, cold, and damp. The chief object of the regimen should be to prevent anæmia; hence plenty of fresh air is essential. Tobacco is injurious. In early life over-exertion and exposure to cold—in adult life, emotional, sexual, and dietetic excesses are the chief dangers. The propriety of marriage must be considered in each case on its merits. Women, as a rule, should not marry; when affected with mitral disease they are often barren. To men marriage is more generally permissible.

Medicinal treatment.—The therapeutical treatment varies according to the stage of the cardiac disease. The mechanical defect of a valve first makes itself felt by shortness of breath, sometimes by palpitation and præcordial pain; these symptoms pass away when compensation is effected, but till then require treatment. In cases of mitral disease, tincture of digitalis (m v doses) relieves the palpitation; spirits of chloroform is also a useful adjunct. In aortic cases, ether and other diffusible stimulants, small doses of opium and belladonna, with the local application of belladonna to the præcordial region, are valuable remedies.

The præcordial pain, mostly retro-sternal, may, when severe, require a few leeches or cupping, but generally yields to mild counter-irritants, such as turpentine, iodine, or mustard. Internally the bromides are useful; when the pain occurs paroxysmally, ethereal preparations and ammonia act well.

When the compensatory changes in the heart are effected, the palpitation and pain decline, and the chief indication is to keep up the nutrition of the heart by the hygienic rules above given, and by the administration of preparations of iron, combined with arsenic, strychnine, quinine, and mineral acids. Chalybeate waters are also useful adjuncts. The syrup, infusion, and tincture of the *Prunus virginica* are preparations of value in some cases after the use of digitalis. The secretions should be carefully watched, and the bowels opened freely every day, so as to avoid straining, and to relieve the portal circulation. The quantity of urine should be daily noted, as it is a capital index of the state of arterial tension. Patients in whom the most perfect compensation exists are, nevertheless, in a state of unstable equilibrium, for an exaggeration of a physiological act or emotion may disturb the balance of the circulation. In most cases the compensation breaks down sooner or later. The pulmonary congestion soon manifests itself by bronchial catarrh, which requires expectorants in various combinations, while friction, poultices, and counter-irritation are applied to the chest-walls.

For the general visceral congestions our chief remedies are, firstly, diuretics; and, failing these, hydragogue cathartics. Of diuretics, the salts of potassium, digitalis, squill, broom, chimaphila, spirit of nitrous ether, and juniper are the most useful. The hydragogue cathartics, which relieve the over-distended portal vessels primarily, and the general circulation secondarily, are also most valuable: of these the compound powders of scammony and jalap in 20- to 40-grain doses; bitartrate of potassium in electuary, one or two drachms, every morning; sulphate of magnesium; and senna are the most trustworthy. By the judicious use of an occasional purgative, and the administration of a suitable diuretic, aided by cupping, poultices; and sometimes a small blister over the loins, combined with rest and stimulants, the worst cases of dropsy from cardiac failure are often saved.

For the dyspnoea and the insomnia, two of the worst symptoms, we have a remedy of great power in the subcutaneous injection of morphia in doses of one-sixth of a grain upwards. This remedy acts often like a charm, and may be used even in the worst cases of both mitral and aortic disease, but always with caution. Albumen in the urine does not necessarily contra-indicate its use. In some cases chloral hydrate and bromide of potassium, alone or in combination, are valuable remedies for the insomnia; and chloralamide in doses of 20-40 grs. is a safe drug which does not cause cardiac depression. Sulphonal and paraldehyde are also useful; but they should be given cautiously. The bromides may be prescribed with other sedatives, such as nitroglycerin, for the dyspnoea. The compressed-air bath also relieves the last symptom.

Dropsy, like the visceral congestions with which it is associated, requires the use of diuretics and hydragogue cathartics. When these fail, the swollen limbs may be punctured with benefit. Continued friction of the limbs, by stimulating the vessels, will often cause considerable anasarca to disappear. The

drug on which main reliance must be placed when general dropsy supervenes is digitalis. It is *par excellence* the cardiac tonic. Convallaria, strophanthus, casca, caffeine, and Adonis vernalis are other drugs having similar action—strengthening, but slowing, the heart-beat. They are all less trustworthy than digitalis. Caffeine is a good diuretic, and so occasionally is convallaria, even when digitalis has failed. Strophanthus is generally the most useful.

Digitalis has so great a share in the therapeutics of heart-disease, and a knowledge of its action is so important, that it must be discussed separately and last. Whatever views may be held as to its physiological action, its greatest triumphs are seen clinically in the treatment of valvular disease, when cyanosis, distended jugular veins, dyspnoea, congested viscera, dropsical limbs, scanty urine, tumultuous heart-action, and a frequent, irregular pulse, indicate failing compensation. This assemblage of symptoms is mostly seen in mitral cases, and it is precisely in this class that the drug is most valuable. Under its use 'the pulse grows in force, fulness, and regularity; the arterial tension rises; the pulmonary congestion diminishes; the kidneys, before inactive, wake up to their work; and the advancing dropsy recognises its master and beats a sullen retreat.' In mitral stenosis these good results are due not only to the increased vigour given by the drug to the contractile power of the heart, but also to the fact that by its slowing action the diastolic period of each revolution is lengthened, and the time thus increased during which the distended auricle can force its contents through the narrowed mitral orifice into the left ventricle. Digitalis here not only obtains a better filling of the ventricle, but a more effective discharge of its contents when filled: and thus, under its use, beat by beat, the general and pulmonary venous congestion is relieved. In mitral insufficiency it is almost equally potent. In both forms certain of its good effects would seem to be due to some influence, probably through the pneumogastric nerves, in producing contraction of the pulmonary blood-vessels. It is perhaps this property which makes it valuable in pulmonary hæmorrhages, independent of heart-disease.

In aortic valvular diseases digitalis is not so valuable a remedy. In these cases the assemblage of symptoms mentioned above is not met with, except sometimes in the later stages, when the mitral valve is secondarily affected, and the case is not one of pure aortic disease. In these compound cases the drug is valuable, especially in combination with ether and ammonia. In aortic insufficiency alone, the slowing action of the digitalis produces evil by increasing the length of the diastolic period of each revolution, during which the regurgitation takes place. The force it may give to the systole is no gain in the face of this slowing action, inasmuch as the aortic recoil gains in the same proportion as the ventricular systole, and thus forces blood back into the ventricle with increased vigour during the lengthened diastole. It is important in aortic insufficiency to maintain the frequency of the cardiac action; hence these cases are so constantly the better for carefully regulated bodily activity; and so, when the toning effects of digitalis are required, it should always be given in combination with ether and ammonia, to keep up quick action of the heart, and to prevent the vertigo and syncope which may otherwise occur. When there is excessive hypertrophy in cases of

aortic insufficiency, digitalis is useful sometimes in quieting palpitation, reducing excessive frequency, and lessening headache and vascular excitement. Caffeine given with senega, aconite in small doses, and Veratrum viride also relieve these symptoms; but a few drops of nitrite of amyl inhaled from cotton-wool, or nitroglycerin tablets, are more rapidly and surely beneficial. In many cases of aortic disease potassium iodide in doses of 3 to 5 grains is a valuable remedy. In aortic stenosis digitalis is rarely required. The simple mode of compensation makes these cases require little treatment. Digitalis is sometimes useful in combination with stimulants to give vigour to the myocardium, and check the tendency to dilatation. If it slows the action of the heart notably, its effect becomes hurtful. Nux vomica often prevents this.

In combined valvular lesions, the predominant lesion must be the guide in the use of digitalis; but it may be given advantageously whenever the general signs of venous stasis are present. The diuretic power of the drug is one of the best tests of its beneficial action. Relying on this test, the writer often gives digitalis for weeks, nay, months at a time, and obtains improvement in the nutrition of the heart which lasts long after its discontinuance. Digitalis effects this improvement by increasing the vigour of the coronary circulation, and thus builds up new heart-muscle to compensate a valvular defect. In aortic cases the nutrition of the muscle must be kept up by iron, arsenic, quinine, strychnine, and stimulants.

The preparations of digitalis which may be used are, the powder in $\frac{1}{2}$ to 1 grain; the tincture in \mathfrak{m} v to xv; and the infusion in \mathfrak{z} j to \mathfrak{z} vj doses. As a diuretic in cases of dropsy, the old combination of squill, digitalis, and blue-pill is invaluable.

B. WALTER FOSTER.

HEART, Wounds of.—SYNON.: Fr. *Blessures du Cœur*; Ger. *Herzwunden*.

ÆTIOLOGY AND ANATOMICAL CHARACTERS.—Wounds of the heart may be punctured, incised, or lacerated; and inflicted with a variety of weapons or other sharp bodies, as well as with projectiles, especially bullets. Traumatic ruptures and contusions form another considerable class of injuries of the heart, which chiefly result from falls, crushing accidents (for example, being 'run over'), kicks and blows. Injuries of the heart due to the entrance of foreign bodies, such as a needle or a bone, have been inflicted in some rare cases from the interior of the œsophagus or stomach; the most remarkable case of this kind being one of a wound of the pericardium from behind by the point of a sword which a juggler had attempted to 'swallow.'

Post mortem, the chest-wall generally presents evidence of the wound that has been inflicted. The pericardium rarely escapes injury. Its sac is found to contain blood in recent cases, or effused lymph or pus when life has been preserved for a few days or more. The walls of the heart at the seat of injury present different appearances, according to the precise nature of the lesion. Punctured and incised wounds may be of all sizes; may take either a direct or an oblique direction through the muscular fibres; and are generally penetrating. Bullet-wounds cut away a portion of the heart, whether at the borders or from the thickness of the organ. Traumatic ruptures present special characters (*see* HEART, Rupture of). In all the varieties of injury

of the heart, the wound is found plugged with blood-clot, the edges being either infiltrated or ecchymosed and torn. In cases that do not prove rapidly fatal, the usual signs of inflammation, or healing, and even cicatrisation, are found in the heart; or aneurysm of the cardiac walls may be developed as a result of the latter. The valves and their appendages are frequently incised or otherwise injured. In some cases a portion of the weapon, projectile, or foreign body may be found in the heart. The ventricles—and especially the right ventricle—are the parts of the heart most commonly injured. The great vessels, lungs, and the arteries of the chest-wall may also be wounded in different instances.

It must be observed that a blow over the heart has proved instantly fatal without leaving any lesion discoverable *post mortem*.

From these results it is evident that wounds of the heart may prove rapidly fatal by loss of blood, by compression of the heart resulting from hæmorrhage into the pericardium, or by shock; while, at a later stage, pericarditis, myocarditis, and secondary hæmorrhage may be expected to supervene.

SYMPTOMS, COURSE, AND TERMINATIONS.—In about one third of recorded cases of injury of the heart, either death is immediate—fainting, convulsions, and the other symptoms of syncope, as well as those of shock, being the prominent phenomena, along with external hæmorrhage; or the patient drops dead after a few moments, during which time he may have undergone considerable exertion. In a second class of cases, the symptoms of syncope or of shock occur immediately, but death does not ensue at once. The patient then lies in a state either of unconsciousness or of complete prostration. In the latter event he complains of a sense of great debility, præcordial oppression, dyspnoea, and suffocation; the surface is cold, pallid, and trembling; vomiting may occur; and there is usually hæmorrhage from the region of the heart. Death occurs after minutes or hours, either from exhaustion, due chiefly to continued or repeated loss of blood, or from compression of the heart. In a third series of cases the course is more protracted. The patient, after suffering from the symptoms just enumerated, but in a less degree, passes through the various phases of constitutional disturbance commonly observed in severe wounds, complicated, however, with pericarditis, myocarditis, and repeated hæmorrhage; and dies of exhaustion after an illness of weeks or months. Lastly, in a small proportion of cases, the patient survives the various accidents and complications just described, and the wound of the heart heals; but it sometimes happens that signs of aneurysm of the cardiac walls, or of incompetence of the valvular apparatus, are developed as the result of the lesion.

DIAGNOSIS.—Wounds of the heart can usually be diagnosed without difficulty by the situation of the external injury and the severity of the symptoms. Similar symptoms may, however, follow injuries of the great vessels in the neighbourhood of the heart, or of the arteries of the walls of the chest, if the hæmorrhage be profuse. Still, unless there be almost complete certainty that a vessel within reach is the only seat of the bleeding, the diagnosis should be left undecided, and all dangerous interference avoided.

PROGNOSIS.—Injury of the heart is generally to be regarded as certain to end in death; but it should not be forgotten that as many as 12 per cent.

of recorded cases are said to have recovered. Some very remarkable instances have occurred of recovery after very severe injury to this organ. The prognosis may be broadly estimated by the severity of the immediate symptoms. Traumatic rupture of the heart is said to have invariably proved fatal.

TREATMENT.—In wounds of the heart, the hæmorrhage must be at once arrested by the usual surgical means; immediate death must be prevented by cautious stimulation; and the patient must be kept in such a condition that, while life is preserved, the danger of inflammatory reaction in the region of the heart, and of fresh hæmorrhage, is reduced to a minimum. It is on this account that restorative measures are to be guardedly employed at first, and stimulants resorted to in the further progress of the case only when urgently indicated. Absolute rest of body and mind is indispensable. Nervine and cardiac sedatives, such as morphine, potassium bromide, chloral hydrate, and belladonna, may be of great service when used with judgment. J. MITCHELL BRUCE.

HEARTBURN.—**SYNON.** : Cardialgia.—Heartburn is a hot or scalding sensation, usually referred to the cardiac orifice of the stomach, but in some cases diffused over the whole abdomen. It is a marked symptom of many forms of indigestion, and is frequently accompanied by eructations of a very acid character: the fluid rejected from the stomach produces a sensation of scalding in the throat and œsophagus. See **DIGESTION, Disorders of**; **FLATULENCE**; and **STOMACH, Diseases of**.

HEAT, Effects of Severe or Extreme.—**(A) Constitutional Effects of Severe Heat acting generally.**—The constitutional or general effects of exposure of the whole body to high temperatures vary with the source and degree of heat, the slowness or rapidity of transition from lower temperatures, and the length of exposure, as well as with the age, constitution, habit, and health of the body; and they are liable to be more or less modified or obscured by various concomitant circumstances and conditions, such as the hygrometric state, and the purity or impurity of the atmosphere.

The range of temperature within the limits of which life can be maintained appears to be greater in the case of man than in that of most of the lower animals, in virtue of greater power of accommodation to external influences, without undue elevation or lowering of the temperature of the body. But in every case any such combination of external circumstances as causes the temperature of the body to rise 10° to 15° above the normal standard speedily proves fatal.

1. **Artificial heat.**—Numerous observations and experiments show that in *dry air* exposure to very high temperatures can be borne, during periods varying with circumstances, without danger or even serious inconvenience, the temperature of the body being kept down within safe limits by evaporation from the surface and from the lungs. Glass-workers, metal-founders, gas-stokers, engineers in steamboats—especially in the tropics—bakers' oven-builders, and others constantly carry on their work in temperatures of from 120° to 160° F. or even higher—to say nothing of the blasts of radiant heat to which some are from time to time exposed. In *moist air*, evaporation from the surface and its cooling influence being diminished or prevented, much lower tem-

peratures speedily become insupportable. Berger was unable to remain in a vapour-bath the temperature of which had risen from 106° to 120° F., although he had easily borne a temperature of 230° F. in dry air for five minutes. When the natural loss of heat is prevented by the moisture of a hot atmosphere—as in a vapour-bath, or by immersion in a hot-water bath, or otherwise—the temperature of the body rises. It has been found, taken in the rectum, to rise as high as 103° in eight minutes in a vapour-bath of 127° ; and in a hot-water bath of 104° to 111° the temperature taken in the mouth has been found to rise to 101.6° .

Fleming found that exposure in the Turkish bath during an hour to a temperature commencing at 170° F. and gradually lowered to about 130° F. caused the temperature of his body (taken by a specially devised thermometer in the mouth) to rise rapidly during the first ten minutes from a normal average of 97.65° to 99.2° F. (a rise of 1.55° F.); and then more slowly until the end of fifty minutes, when the highest point, 101.3° F. (a rise of 3.65° F.), was reached. His pulse rose during the first ten minutes from 78 to 91 beats in the minute, and like the temperature attained its maximum, 115, at the end of fifty minutes. His breathing first diminished in rapidity from 22.5 to 20.8, and then increased to 25.4 in actual rapidity, but maintained a diminished ratio to the pulse. The arterial tension seemed to be increased by the greater rapidity of the heart's action, combined with the engorged state of the capillary circulation. The quantity of material eliminated during the hour amounted to forty-four ounces. The proportion of chlorides in the urine passed after the bath (3.65 in the 1,000) was little more than half that in the sweat (6.05) collected during the bath, and much less than in the urine previously passed (5.68). The proportion of urea in the urine was slightly increased, and the sweat contained 1.55 in the 1,000.

The effects felt by those exposed to great heat vary with the temperature, the length of exposure, and collateral circumstances, such as an impure atmosphere and physical exertion, &c. A sensation of warmth, at first agreeable, is succeeded by one of oppressive and then painful heat, until this is again relieved by the establishment of copious evaporation from the surface. Pleasant stimulation, and some degree of excitement of the nervous and muscular systems, are quickly followed by languor, lassitude, listlessness, feelings of exhaustion, indisposition to mental effort or muscular exertion, dizziness, tendency to sleep, faintness, and unconsciousness, sometimes accompanied or preceded by convulsions. If relief is not afforded death ensues. If timely relief is afforded, more or less speedy and complete recovery may be brought about.

If the symptoms have been severe and persistent, or if the sufferer has been exposed to repeated attacks, permanent damage to the health, and especially to the nervous system, almost certainly results, in spite of apparent temporary recovery. In many cases general debility and deterioration, in some cardiac troubles, and in others insanity, have been recorded as the persistent after-effects. Symptoms and conditions closely or exactly resembling those of sunstroke may be produced by exposure to an artificially heated atmosphere, or to blasts of radiant heat from fires or furnaces. See **SUNSTROKE**.

Bernard, Delaroché, and others have shown that

animals exposed to temperatures of from 130° or lower to 150° F. and upwards quickly die.

The *post-mortem* examination of animals so killed showed that the heart had entirely ceased to beat a few seconds after death, and that neither it nor the muscular coat of the intestines could by any means be stimulated to contract again. The muscular fibres of the heart examined microscopically appeared rigid and coagulated (Kühne and Ranvier). Further, the blood in both arteries and veins was dark-coloured. *Rigor mortis* set in almost directly after death, and general decomposition very speedily commenced. Apart from these changes no lesions sufficient to explain the cause of death can be seen. The proteids of the nervous and muscular systems begin to undergo coagulation at 116·6° F. (47° C.), or even at a considerably lower temperature, if the exposure is prolonged. Such a coagulation in the nerve-cells and muscle-fibres would cause chemical and physical changes incompatible with life.

ANATOMICAL CHARACTERS.—The *post-mortem* appearances met with in the human subject in cases in which death has been attributed to the general effects of heat have not been uniform, probably because there has been in most cases simultaneous exposure to other deleterious influences. It is probable that the changes leading to the fatal issue are microscopic, and are to be found chiefly in the nervous system. Recent observations by Goldscheider and Flateau, Marinesco, and Mott have shown that changes can be seen in the structure of the nerve-cells of animals and men who have died with hyperpyrexia. Nissl-bodies, composed of a nucleo-albumen, are not visible in such cases.

TREATMENT.—The *immediate treatment* to be adopted in the case of those suffering from exposure of the whole body to heat consists essentially in removal into a cooler and purer atmosphere; quiet rest in the recumbent position; fanning; cool or even cold affusions or sponging, especially over the head and spine—the effect, however, being carefully watched; and the administration of cool or lukewarm fluid in small quantity at a time, with some stimulant. Copious draughts of cold water in a highly heated state of body are liable to give rise to dangerous or even fatal results. Bleeding is not to be recommended.

The *after-treatment* must be conducted on general principles, and determined by the condition of the patient, and the indications afforded in the particular case.

2. Climatic and Solar Heat.—The effects of climatic heat experienced on transition from temperate to tropical regions are as follows: 1st. The average temperature of the body rises 5° to 1° F. according to Davy and Crombie, or to a somewhat greater extent according to others. The daily fluctuations of bodily temperature in health in India correspond to those in England. The normal temperature of native Indians is about half a degree higher than that of Europeans (Crombie). 2nd. The pulse is quickened according to most observers, but Rattray says this is incorrect. 3rd. The breathing becomes slower and less deep, falling from about sixteen to about twelve or thirteen per minute. Less carbonic acid and less water are exhaled. 4th. The skin acts much more freely, its excretion being increased by about 24 per cent. (Rattray). The continued hyperæmia and over-action of the skin, however, are liable to be followed by congestion and obstruction of the sweat-

ducts, giving rise to 'prickly heat.' 5th. The urine is lessened in quantity, and the urea and chlorides are diminished proportionately to the temperature as the latter rises from 70° F. to 90° F. 6th. The appetite, especially for animal food, is diminished, and the digestive powers seem lowered. 7th. Indisposition to exertion and a sense of exhaustion of mind and body are experienced in degrees varying with circumstances; the depressing effects being most felt when the heat is not only great but continuous day and night, and when the atmosphere is moist.

The effects of the radiant heat of the sun, as distinguished from those of atmospheric heat, are discussed in the article on **SUNBURN**.

Exposure to the direct rays of the sun, or to great or continued heat in the shade, especially under unfavourable atmospheric and general conditions, may give rise to heat-fever, heat-apoplexy, or one or other of the forms of sunstroke. See **SUNSTROKE**.

(B) Local Effects of Severe Artificial Heat: Burns and Scalds.—The local effects of heat vary with the degree, the length of exposure, the medium of application, and the part acted upon. *Burns* result from 'dry,' *Scalds* from 'moist' heat.

SIGNS AND SYMPTOMS.—(1) A comparatively slight degree of heat causes redness, tingling, pain, and tenderness, which soon subside. Desquamation of the epidermis may follow, but no permanent trace of injury is left. (2) A higher degree causes severe burning pain, and great redness of surface, followed by effusion of serum beneath the cuticle (vesication). Complete restoration without scar is usually effected. (3) Still higher degrees of heat or longer exposure cause intense pain, and immediate destruction of the true skin to a greater or less depth. Permanent scarring results. (4) Violent heat and prolonged exposure cause death and charring of the skin and structures beneath it down even to the bone. Loss of parts and more or less serious deformity and scarring necessarily result.

Only too frequently, in spite of such precautions as it is possible to take, the sloughs of burns become infected, pus forms, and sometimes widespread and destructive cellulitis develops. But suppuration is no necessary result of a burn.

The separation of sloughs, and the processes of repair after severe burns, take place slowly; and as a rule the patient suffers much more acutely, and during a much longer period, than after other forms of injury involving equally extensive destruction of tissue.

The *constitutional symptoms and effects* associated with burns and scalds vary with the superficial extent and situation, rather than with the depth of the injury. Thus an extensive burn or scald over the abdomen affecting only the skin is much more likely to prove fatal than charring part of an extremity; and burns over the front of the abdomen or chest are more likely to prove fatal than those of similar extent on the back. If half the surface of the body is even superficially affected the sufferer rarely recovers. Children suffer more than adults, and old age is unfavourable.

In severe cases death may result from shock, either immediately on receipt of the injury, or after a period of from two or three to forty-eight hours or more. During such time the sufferer remains in a state of collapse or prostration, with pale face, low temperature (due chiefly to decreased produc-

tion, partly to increased loss, of heat when epidermis has been widely removed), cool breath, small frequent pulse, dry tongue, and scanty urine; sometimes the patient is apathetic, at other times excitable and restless; thirst is common, vomiting occasional, convulsions or delirium rare. Hæmoglobinuria may be found. *Post-mortem* examination shows congestion of the viscera, especially the brain. The kidneys may have a reddish-brown colour, largely due to blood-pigment in the tubules. During life red corpuscles altered in form and even broken up have been seen; and after death the blood has often been described as thick, and thrombosis of vessels in many organs has been found.

More than fifty per cent. of the fatal cases occur within forty-eight hours, and the majority seem to be rightly attributed to *shock*. But there may be many contributory causes of greater or less importance. Thus Sonnenburg thinks some almost immediate deaths may be due to over-heating of blood and consequent paralysis of the heart. Other possible factors are: carbon dioxide; destruction of red corpuscles and accumulation of solution of hæmoglobin, forming a fluid which is destructive of leucocytes, thus setting free fibrin-ferment (leading to thrombosis) and other less-known toxic substances; and the accumulation in the blood of toxic materials which should be removed by kidneys and skin.

In about forty-eight hours, more or less, the stage of reaction sets in. The patient revives, and some degree of general pyrexia becomes manifest. Too often it is of septic type, and is accompanied by inflammation and suppuration of the burnt part. An acute septicæmia with erythematous or scarlatiniform rashes is not uncommon in children. The tendency to congestion of the abdominal and thoracic viscera persists, and sometimes runs on to actual inflammation (septic or toxic?). But the most singular lesion of this period is ulceration of the duodenum between the pylorus and the papilla of Vater. The presence of such an ulcer may be indicated by epigastric pain after food, and perhaps hæmatemesis or mælena. Often perforation into the peritoneum or fatal bleeding from an eroded artery occurs without warning. The complication is rare and not necessarily fatal. Embolism of a small artery and autodigestion is a suggested explanation of the occurrence, but not of the localisation of the ulcer. William Hunter produced similar ulcers in dogs by the intra-venous injection of toluylene-diamine, and suggests that in burns the cause may be a toxin eliminated with the bile. During this period, and from the causes indicated, death occurs in about 30 per cent. of the fatal cases.

In a fortnight or so, as a rule, acute sepsis will have subsided, many sloughs will have separated, granulation and suppuration will have become established, and healing will gradually take place. But large sloughs take weeks to separate, and where the deep fascia is opened serious cellulitis may cause much trouble and chronic fever; or the patient may sink, worn out by suffering, and exhausted by the profuse discharge from the suppurating surface, or by persistent diarrhoea, accompanied or not by blood in the motions. Sometimes the kidneys are affected, and blood and blood-casts may be found in the urine. Pyæmia, erysipelas, or tetanus may occur and cause death; but there would not appear to be any special liability to these diseases after burns or scalds.

TREATMENT.—1. *The Relief of Pain.*—It is said that the pain of slight burns may be relieved by plunging the part into cold water, or into hot water, or by holding it in front of a fire. Elevation of the part, gentle compression with some soft material, and uniform warm temperature act best. In more serious cases suffering should be relieved by morphine hypodermically.

2. *The Dressing.*—When hyperæmia only is induced protection of the part by a bandage over a thin layer of wool or gauze is sufficient. When vesicles rise, they should be somewhat freely opened and their contents evacuated; but the epidermis should not be removed, as it forms the best protection to the subjacent rete. Careful handling is necessary to avoid denudation of raw surfaces. Clothes should be cut rather than pulled off, and in bad cases their charred remains are best floated off in a hot bath.

When once vesication has been caused, the possibility of infection arises. The first object of the dressing is to prevent this: it must absorb any discharge, prevent its decomposition, and be comfortable. Some recommend that the burnt area shall be gently washed with a feeble antiseptic, such as boric acid or dilute carbolic lotion. If the parts have not been sterilised by heat, they will not be by such applications. In limited cases, some attention may be paid to the cleansing of skin around the injured area.

The early dressings, especially of burns destroying only the surface of the skin, are often excessively painful, so that anaesthesia is necessary in children and may be so in adults. The less frequent the dressing, therefore, the better. Ointments and oily preparations absorb nothing, do not mix with discharges, and do not prevent their decomposition. Such dressings only cover the burns, protect them from mechanical irritation, and peel off more or less easily.

The choice of dressing lies really between a 'dry' dressing and one kept moist by a covering of waterproof tissue. The former is the better if it can be successfully worked. It should consist either of simple sterilised gauze or of double cyanide gauze wrung as dry as possible out of 1:2000 perchloride of mercury lotion. Either should be applied several layers thick, and should be covered with a good layer of salicylic or other wool and fixed with a bandage. Such a dressing absorbs discharges and prevents decomposition of them chiefly by dryness due to ready evaporation. If the discharge is at all free it is as well to place deep in the gauze a layer of some powder, such as aristol, or equal parts of powdered boric acid, zinc oxide, and kaolin. Under this treatment thin superficial sloughs are dried and gradually cast off, granulation and healing taking place beneath them. So long as the patient is comfortable and the temperature normal, such a dressing may be left. When it is necessary to change it, the wool and as much gauze as can be removed without pain is taken off: the rest is thoroughly soaked with warm sterile saline solution from a syringe or in a bath.

Another good form of dry dressing is the following. In cases in which the whole thickness of the skin is not destroyed, lint soaked in a saturated solution of picric acid may be uniformly applied to the burnt surface, after opening all vesicles, and allowed to dry on under a layer of cotton wool.

Sometimes, however, infection of the sloughs

occurs, pus accumulates beneath them and does not escape readily into the dry dressing, but accumulates in contact with the living tissues. Pain and fever result. If removal or partial removal of the slough is practicable, it may yet be possible to use a dry dressing, or to revert to it after short employment of a moist dressing.

The moist dressing consists either of several layers of gauze or of two or three of boric lint wrung very dry out of boric lotion or a dilute mercury lotion. This is covered by a layer of oiled silk projecting half an inch beyond the lint in all directions; over this are placed a layer of wool and a bandage. This dressing quickens the separation of sloughs, facilitates the escape of discharges, and prevents their decomposition; but to accomplish these results the dressing must be changed once, twice, or more frequently during the twenty-four hours, and this may be a painful process.

3. *Removal of Dead Parts.*—Parts of limbs which have been completely charred, or which have lost so much skin that recovery with usefulness is impossible, should be removed by amputation as soon as shock permits. But when there is doubt as to the completeness of destruction of the skin, as is often the case in both burns and scalds, an antiseptic dressing must be applied until the evidence on this point is clear. Sloughs should be removed if discharge is bagging beneath them.

4. *The Prevention of Deformity.*—The more slowly a granulating sore heals, the more deeply does the granulation-tissue penetrate, and the greater is the resulting contraction. Speedy healing should, therefore, be aimed at in all cases of wide destruction of the epidermis by Thiersch's method of skin-grafting. An affected limb must be kept upon a splint until healing is complete, occasional opportunities for performing the movements of the fixed joints being allowed. It is said that the permanent warm bath diminishes contraction. For the remedying of deformities due to burns, plastic operations are often necessary.

5. *The Treatment of Shock.*—In extensive burns, even though superficial, the immediate danger to life is great. It must be met by keeping the patient in a bath at about 105° F., by the free infusion of saline solution into veins or subcutaneous tissue, the hypodermic injection of strychnine, and the administration of hot milk and coffee or of hot brandy and water. See SALINE SOLUTIONS, Infusion of.

M. S. PEMBREY. STANLEY BOYD.

HEAT, Therapeutic Use of.—Heat is employed in the treatment of disease as a general or local stimulant, a caustic, or a counter-irritant; and that in the form either of *dry* or of *moist* heat. See BATHS; COLLAPSE; CHOLERA; COLIC; COUNTER-IRRITANTS; FOMENTATIONS; POULTICES; and RESUSCITATION.

HEAT-STROKE.—A synonym for sunstroke. See SUNSTROKE.

HECTIC FEVER. See FEVER; and TEMPERATURE.

HELMINTHIASIS (ἐλμινς, a worm).—Disease characterised by the presence of worms.

HELMINTHS (ἐλμινς, a worm).—See ENTOZOA.

HELOUAN, near Cairo, Egypt.—Thermal sulphurous muriated saline waters. See MINERAL WATERS.

HEMERALOPIA.—DEFINITION. — Day-blindness: a disorder of vision in which objects cannot be seen well or comfortably in ordinary daylight or by strong artificial light, but are seen more clearly or more comfortably in shade or in twilight.

Most modern authors use the term in the opposite sense of *night-blindness*, regarding it as derived from *ἡμέρα*, the *day*, and *ὤψ*, the *eye* or *sight*. In this work it has, from the first, been used in the sense given above, the *al* being regarded as representing *alpha privativum*, or as a contraction of *ἀλαός*, *blind*. This meaning has since been adopted in the *Nomenclature of Diseases* of the Royal College of Physicians. It has long been used as the antonym of *Nyctalopia*. See NYCTALOPIA.

CAUSES.—Day blindness is a symptom rather than an idiopathic affection, and is sometimes the effect of mere intolerance of light (photophobia), dependent upon irritation or inflammation of the cornea, &c. The various causes may be grouped as follows:—

1. Opacity in some of the refractive media, such as central nebula or leucoma of the cornea, or circumscribed opacities occupying the pupillary region of the lens or the vitreous. In such cases, vision is obscured when the pupil is contracted, but becomes clearer when the pupil dilates in shade. 2. Irritation or inflammation of the parts of the eye innervated by the sensory fibres of the fifth nerve—the lids, the conjunctiva, the cornea, or the iris; neuro-pathic affections of these structures; and reflex irritation from nose, teeth, uterus, &c. 3. Hyperæsthesia of the retina, which may be due to reflex irritation, or (rarely) to inflammation of the retina, the optic nerve, or the choroid, to insufficient pigmentation of the ocular fundus as in albinism, to dazzling from coloboma of the iris or preternatural dilatation of the iris from any cause, to exposure to bright lights or glare of any kind, to prolonged seclusion in darkness or dimly lighted places. A transient physiological form of hemeralopia occurs whenever the eyes suddenly pass from darkness into bright light.

TREATMENT.—The treatment of hemeralopia should follow the special indications. Impairment of sight due to central opacity in any of the refractive media may often be relieved by dilatation of the pupil with a weak solution (gr. $\frac{1}{20}$ to gr. $\frac{1}{2}$ to an ounce) of atropine or other mydriatic, or by making an artificial pupil. Inflammations of the various structures of the eye and reflex irritations are to be treated by appropriate means. The eyes should be protected by a shade or by neutral-tinted glasses. The general treatment must be adapted to the associated local and constitutional conditions.

JOHN TWEEDY.

HEMIANÆSTHESIA (ἡμι-, half; ἀ-, priv.; and αἰσθάνομαι, I feel).—Paralysis of sensation, affecting one side of the body. See SENSATION, Disorders of.

HEMIANALGESIA (ἡμι-, half; ἀ-, priv.; and ἄλγος, pain).—Insensibility to painful impressions, affecting one side of the body. See SENSATION, Disorders of.

HEMIANOPIA (ἡμι-, half; ἀ-, priv.; and ὤψ, sight).—The term 'hemiopia' is now generally

taken to mean loss of perceptive power in one lateral or vertical half of the *retina*; while by hemianopia is understood obscuration of vision on one lateral or vertical half of the *visual field*. Thus, owing to the fact that rays of light cross within the eye, right lateral hemianopia is produced where left lateral hemiopia exists, as a result of intracranial disease of one or other kind. See NERVOUS SYSTEM, Examination of.

It is well known that in the lower vertebrate animals the optic nerves undergo a complete decussation at the optic chiasma, so that all impressions from each eye go to the opposite optic lobe. Some authorities believe that a similarly complete decussation of the optic nerve-fibres takes place at the chiasma in man; but the majority adopt the view that at the optic chiasma there occurs a semi-decussation only. It seems quite possible that these discrepancies in doctrine may be in part dependent upon the fact that the course of the optic fibres is not the same in all cases. There may, in fact, be variations in the degree of completeness of the decussation of the optic nerve-fibres at the chiasma, just as, from the researches of Flechsig, we now know that not infrequently considerable variations occur in the amount of decussation of motor fibres in the anterior pyramids of the medulla.

The effects resulting from congenital or early blindness of one eye supply us with some information bearing upon this point. Where a semi-decussation exists, the effects of the atrophy of the optic fibres proceeding from the affected eye should, beyond the chiasma, be pretty equally distributed, so that, though in such a case the two optic nerves will be very dissimilar in size, the optic tracts ought to be of equal bulk; and this is what is most commonly met with. On the other hand, it is undoubtedly the fact that in some of such cases the optic tract on the opposite side is found to be notably atrophied, while that on the same side as the atrophied optic nerve presents a healthy appearance—signs which betoken a pretty complete decussation of the optic fibres at the chiasma.

Different forms of Hemianopia and their causes.—In the cases where the common arrangement obtains—that is, the semi-decussation—it seems to be the inner fibres that cross one another, while the outer fibres of each nerve are continued on into the outer part of the corresponding optic tract. The result of this arrangement would be that the fibres from the right half of each retina would proceed to the right optic tract, while those from the left side of each retina would go to the left optic tract; so that if the image of any object should fall simultaneously either on the right side of the two retinæ, or on the left side of the two retinæ, the impressions in either case will be transmitted along one and the same tractus opticus—the right or the left, as the case may be. Therefore it seems clear that, in all cases in which the semi-decussation of the optic fibres obtains, any intracranial lesion which either destroys, seriously presses upon, or disturbs the nutrition of the optic tract on one side, will give rise to an opposite *lateral hemianopia*. If the decussation had chanced to be total, there would, on the contrary, have been produced a ‘crossed amblyopia.’

The optic tract is apt to be involved in some part of its course between the chiasma and the geniculate bodies by different kinds of lesions. Thus, we may have tumours originating in parts of the tract itself; or the tract may become involved secondarily, or

pressed upon, by some tumour or hæmorrhage occurring in the *crus cerebri* or in the posterior tubercle (pulvinar) of the thalamus, or by a tumour originating in the inner and under part of the temporal lobe, or from the bone itself in the middle fossa of the skull.

Two other, much rarer, forms of hemianopia require to be mentioned, which are produced by lesions affecting different parts of the chiasma. One of these is double *temporal hemianopia*, which may be produced by a lesion pressing upon the anterior median portion of the chiasma. Any lesion capable of doing this would probably be a tumour, and it would produce the same effects whether there is a total or a semi-decussation in the chiasma. The lesion would involve the decussating fibres that come from the inner half of the retina on the two sides, and thus would lead to double temporal hemianopia. The other form is known as *nasal hemianopia*, and where semi-decussation of the optic fibres exists it would be produced by a tumour or an aneurysm causing an injurious amount of pressure upon either outer angle of the chiasma, since there would then be paralysis of the fibres emanating from the outer part of the retina, and consequently the suppression of the inner part of the visual field of the corresponding eye. It is only with extreme rarity that this form of hemianopia is double.

We have now to turn to another side of the question. It is natural to ask whether the lateral hemianopia that develops as a consequence of disease of the optic tract will also result from a lesion which involves the optic fibres beyond the *corpora geniculata*—that is, in their deep intracerebral course. This was the view put forward by von Graefe in 1860, and one which was very commonly accepted till it was challenged by Charcot some few years since. Relying apparently upon the paucity of cases on record in which lateral hemianopia had resulted from lesions of the cerebral hemispheres themselves, and upon the many cases that had come under his own observation in which ‘crossed amblyopia’ had been produced by functional or structural lesions involving the posterior or sensory segment of the internal capsule, he came to the theoretical conclusion that all the optic nerve-fibres from each eye went to the opposite cerebral hemisphere, owing to the supposed fact that those fibres which had not decussated at the chiasma did decussate somewhere in the *corpora quadrigemina*. These views he embodied in a well-known diagram. The subsequent progress of knowledge has, however, not been compatible with this theory. Thus Munk’s original statement has been confirmed by Schäfer and S. Brown, to the effect that removal of one occipital lobe in the monkey produces, not crossed amblyopia, but opposite lateral hemianopia. Again, Seguin has shown that opposite lateral hemianopia is more especially produced by lesions in that inner portion of the occipital lobe known as the ‘cuneus,’ a region supplied by a rather large branch of the posterior cerebral artery which passes along the calcarine fissure. Still it would appear that lesions anywhere in the posterior parietal, temporal, or occipital region of the hemisphere, when they implicate the ‘optic radiations’ of Gratiolet (i.e. fibres passing backwards from the *corpora quadrigemina* and *geniculata* to the occipital cortex), are also capable of producing an opposite hemianopia in man of a permanent character. In the lower animals (monkey, dog, &c.), for the production of a similar defect the removal of the occi-

pital lobe must be complete, and even then the defect is of a comparatively brief duration—two or three weeks at most.

There is at present an apparent contradiction between these well-attested facts, as to the production of lateral hemianopia from disease of the occipital lobe (implying as they do that the semi-decussation persists even to the cortical termini of the optic fibres), and the fact of the existence of a 'crossed amblyopia' in association with functional or structural disease of the hinder portion of the internal capsule. A solution of this difficulty cannot as yet be readily found. Ferrier still maintains that crossed amblyopia is produced by destruction of one angular gyrus. He asserts, indeed, that 'the angular gyri are more particularly the centres for clear vision, each mainly for the eye of the opposite side.'

DIAGNOSIS.—Under this head reference has to be made to different sides of the problem. The first point to be considered is the mode of recognition of the different varieties of hemianopia. In some cases, where the defect is well marked, and the patient is intelligent, he will himself call the observer's attention to it; very frequently, however, such defects are only discovered by being specially looked for. This subject will be referred to under **VISION, Defects of**. Here it must suffice to say that for all accurate observation an instrument named a 'perimeter' is required, by the aid of which the exact nature and extent of the limitation of the visual field can be discovered; but, for a first rough examination, the following simple method will suffice for the detection of any great narrowing of the visual field in particular directions. The patient stands with his back to the light, and, covering one eye, looks steadily from a distance of eighteen inches at the nose or eye of the observer, who then moves his forefinger about in different parts of the field of vision, and notes any part where the patient says it is invisible or badly seen. Anything like a hemianopic defect, of either variety, may be easily appreciated in this manner.

The fact of the existence of hemianopia having thus been established, we must next seek to determine the site of the lesion by which it has been caused. The problems of regional and of pathological diagnosis are in these cases often intimately related to one another. With respect to the latter problem some hints have already been given.

For purposes of regional diagnosis the first thing is to determine whether the case before us belongs to one of the other of two main categories into which cases of hemianopia are divisible—that is, whether it is a case of '*tract*' or of '*central hemianopia*'; and this may be determined by a delicate test first used by Wernicke. This test is based upon the fact that, in the case of lesions in the primary optic centres of one side (the corpus geniculatum and one anterior quadrigeminal body), or of their afferent fibres, there is an interference not only with visual impressions, but also with the path for impressions that excite pupillary contractions through these oculo-motor centres; whereas in the case of deeper lesions, situated in parts of the cerebral hemisphere involving either the optic radiations or the occipital cortex, the pupillary reflex would not be at all interfered with. Thus in cases of '*tract hemianopia*' there exists what has been termed hemiopic pupillary inaction; while in cases of '*central hemianopia*' this sign does not exist. The sign itself is

sought for by throwing a pencil of light obliquely (at an angle of 40° – 60°), by means of an ophthalmoscope mirror, on to the blind side of the retinae, so as to see whether contraction of the pupil is, or is not, produced. If carefully performed, no reaction of the pupil occurs in cases of '*tract hemianopia*'—that is, where the defect is due either to disease of the afferent fibres, or of the primary optic centre itself. But where the hemianopia is caused by disease in the cerebral hemisphere itself (*central variety*) the contraction of the pupil occurs equally well whether the light be thrown upon the blind or upon the unaffected half of the retina.

From the point of view of a regional diagnosis, we may enumerate four fairly marked types of '*central hemianopia*'.

1. There are cases in which hemianopia exists alone, or as the most prominent symptom, or in association with certain general signs indicative of the existence of tumor cerebri. Such are the cases where the occipital lobe is affected in or about the region of the cuneus.

2. Cases in which hemianopia co-exists with hemianæsthesia and choreiform or ataxic movements of one half of the body, without marked hemiplegia. These are probably due to a lesion of the caudo-lateral part of the thalamus, or of the caudal division of the internal capsule, on the side of the brain opposite to the dark half-fields and the hemianæsthesia.

3. Cases of hemianopia with complete hemiplegia and hemianæsthesia are probably caused by an extensive lesion of the internal capsule in its knee and caudal part.

4. Cases of hemianopia with aphasia and hemiplegia, with or without hemianæsthesia, are probably due to an extensive superficial lesion of the area supplied by the left middle cerebral artery, such as may be brought about by its plugging either from thrombosis or embolism.

In all these cases the pupillary reaction would not be interfered with, and there would be no atrophy of the optic nerves unless as a sequence of choked disc. In addition to these forms, five types of '*tract-hemianopia*' may be enumerated.

1. The first type of tract-hemianopia would be caused by lesions in the primary optic centres on one side (the corpus geniculatum and one anterior quadrigeminal body). Little or nothing is known of lesions thus limited, which are excessively rare. Still, such parts may be involved primarily or secondarily, by a tumour; when among a varying group of symptoms we might have, as results of the lesion in the parts specified, lateral hemianopia, hemiopic pupillary inaction, together with early atrophy of the optic nerves.

2. In other cases where disease involves the optic tract and the crus cerebri, we may have hemianopia co-existing with some form of cross-paralysis. A probable combination would be paralysis of the third, fourth, and sixth cranial nerves on the side of the lesion (some one or all of these nerves), together with partial hemiplegia (without anæsthesia), and hemianopia on the opposite side. In some cases choked discs would appear early, without interfering with the hemiopic symptoms until optic atrophy with complete blindness had become established.

3. In cases where the optic tract is involved more anteriorly, other symptoms co-existing with the hemianopia may be very vague and uncertain;

but the hemiopic pupillary inaction should be marked, and there should be early partial atrophy of the optic nerves. These latter signs suffice to distinguish this group of cases from those belonging to the first category of 'central hemianopia,' with which otherwise they might be confounded.

4. Cases of bitemporal hemianopia due to lesions pressing upon the anterior part of the chiasma.

5. Cases of nasal hemianopia, mostly single, due to a lesion involving the outer part of the chiasma.

The only other forms of monocular hemianopia are also very rare, and are due to lesions of the optic nerve itself in front of the chiasma.

Other very rare forms of hemianopia affect the superior or inferior, rather than the lateral, segments of the field of vision. As Seguin points out, when these forms exist with a very irregular demarcation-line, they are probably still more peripheral in their origin and due to embolism or thrombosis of the central artery of the retina.

In another class of cases, instead of a definite hemiopic defect of sight, we meet with partial, quadrant- or sector-like defects in the upper or lower halves of the visual fields. Little or nothing is known as to the causation of such defects. They might conceivably be caused by disease in certain limited portions of the occipital cortex, or of some only of the fibres constituting the optic radiations. Again, they might be due to a localised damage to some of the fibres of one crus or one optic nerve; or to degeneration of the retina caused by the plugging of some one branch of its central artery.

PROGNOSIS AND TREATMENT.—Nothing special can be said under these heads concerning the hemianopia itself. Both the prognosis and the treatment of this defect are absolutely dependent upon the causative conditions, and the nature and severity of the collateral symptoms with which it is associated. It may in some cases not be dependent upon an actual organic lesion, but be one among other indications of mere functional defect. We must, in fact, always seek to mitigate or remove the underlying causal conditions, and upon our chance of being able to do this the prognosis in any given case entirely depends.

H. CHARLTON BASTIAN.

HEMICRANIA (*ἡμι-*, half; and *κρανίον*, the head).—Pain limited to one side of the head. The term is, however, generally used as synonymous with *migrain*. See *MEGRIM*.

HEMIOPIA
HEMIOPSIA } (*ἡμι-*, half; and *ὥψ*, sight). -

A loss of perceptive power in one lateral or vertical half of the retina. See *HEMIANOPIA*; and *VISION*, Disorders of.

HEMIPLEGIA (*ἡμι-*, half; and *πλῆσσω*, I strike).—Paralysis of motion of one side of the body; sometimes applied to loss both of motion and of sensation. See *PARALYSIS*; *BRAIN*, *Hæmorrhage* in the; *BRAIN*, *Softening* of; *BRAIN*, *Tumours* of, &c.

HEPATALGIA (*ἥπαρ*, the liver; and *ἄλγος*, pain).—Strictly this word signifies pain in connection with the liver. It has, however, been specially applied to a supposed neuralgic pain referred to this organ, coming on in paroxysms, and said to be of a severe character in some instances, so as to simulate hepatic colic. Whether there is any such

affection is exceedingly doubtful; and probably in cases of supposed hepatalgia the neuralgia is either superficial, or there is some tangible but undiscovered cause for the pain, connected with the hepatic apparatus or some neighbouring structure. See *PAIN IN VISCERAL DISEASE: Coloured Plates*.

FREDERICK T. ROBERTS.

HEPATISATION (*ἥπαρ*, the liver).—A term applied to the condition produced by acute inflammation of the lung, in which the pulmonary substance becomes solid and friable, somewhat resembling the liver in its physical characters. See *LUNGS*, *Inflammation* of.

HEPATITIS (*ἥπαρ*, the liver). Inflammation of the liver. See *LIVER*, *Inflammation* of.

HEPATOCELE (*ἥπαρ*, the liver; and *κῆλη*, a tumour). Hernia of the liver. See *Liver*, *Displacements* of.

HEPATOPTOSIS.—See *LIVER*, *Malformations* of.

HERCULESBAD (HERCULES-FURDO), in Hungary.—Thermal sulphur and muriated saline waters. See *MINERAL WATERS*.

HEREDITARY ATAXIA.—Hereditary Cerebellar Ataxia. See *FRIEDREICH'S DISEASE*.

HEREDITY.—By heredity is meant that special property through which the characters and qualities of organisms are transmitted to their descendants throughout successive generations, so that the offspring in their main features resemble their parents. The transmission of parental characters to offspring is a subject for scientific inquiry. It has long been known that a young organism is derived from an ovum formed within the body of the female parent, so that a descent from the mother and a direct continuity through the egg with her structure was apparent. But it is within a comparatively recent period that the direct participation of the male parent in the production of the offspring has been traced. The older writers thought that the semen evolved a vapour or spirit, which influenced the ovum, or that the fluid part of the semen penetrated the vitelline membrane, and induced germinative changes, which resulted in the production of a young organism, without the male contributing any definite structure in the process. The discovery, in 1842, by Martin Barry, of the penetration of the vitelline membrane by the spermatozoon put the subject on a more definite basis, and the researches of Bütschli, Auerbach, Föl, Strasburger, Flemming, Hertwig, E. van Beneden, and others, have given greater precision and completeness to our conceptions of the process of impregnation. It has now been demonstrated that the young organism arises within the egg by the incorporation, or conjugation, of an extremely minute particle derived from the male parent with an almost equally minute particle derived from the female parent. The particle derived from the male is the head of the spermatozoon, which, after it has penetrated within the ovum, is called the male pronucleus. The particle derived from the female is a portion of the germinal vesicle, which has remained included within the egg, and is called the female pronucleus. The male and female pronuclei gradually approximate, touch, and then become incorporated with each other, and

form what is called the segmentation-nucleus. The segmentation-nucleus consists of chromatin-fibres and nucleoplasm, which are derived both from the nucleus of a male sperm-cell, i.e. the head of a spermatozoon, and from the nucleus of a female germ-cell, i.e. the germinal vesicle. The segmentation-nucleus is therefore a composite or hermaphrodite nucleus, and consists of matter derived from both parents. This composite nucleus then rapidly divides and subdivides within the ovum, so as to produce daughter-nuclei, and the protoplasm of the yolk undergoes a corresponding process of division. Each of the daughter-nuclei becomes surrounded by a layer of protoplasm, and numerous new cells are produced. The nucleus of each of these new cells contains chromatin-fibres derived from the segmentation-nucleus, and through it from the corresponding fibres of the nucleus of the male sperm-cell and of the female germ-cell. It is believed that the male and female chromatin-fibres enter in equal proportions into the structure of the nuclei derived by division from the segmentation-nucleus, so that each of the nuclei of the new cells, like the segmentation-nucleus, is composite or hermaphrodite, i.e. represents both parents. The cells produced by the division of the segmentation-nucleus and its envelope of yolk-protoplasm form the blastodermic membrane. In man and the higher organisms this membrane consists of three layers of cells, named epiblast, mesoblast, and hypoblast. From these layers, by a continuous process of division and subdivision of the nuclei of their constituent cells, accompanied by a differentiation of the protoplasm, all the tissues and organs of the body are descended. As the nuclei of all the cells in the body are derived by continuous descent from the nucleated cells of the blastoderm, and as these again are the descendants of the segmentation-nucleus, one may infer that the nucleus of each cell is composite or hermaphrodite and represents both parents.

The changes which take place in a nucleus during its division constitute the process of *karyokinesis* or *karyomitosis*. They consist at first in an enlargement and rearrangement of the chromatin-fibres of the nucleus, and then in a splitting of each fibre into two daughter-threads, so that each daughter-thread divides itself equally between the two daughter-nuclei which are formed by the splitting of the parent-nucleus. As this process goes on throughout the whole period of cell-multiplication, there is an actual transmission of structure from the segmentation-nucleus to the nuclei of all the cells derived both directly and indirectly from it. Now, as this descent in structure is in all probability associated with a power of transmitting properties, and as the segmentation-nucleus consists of material derived from both parents, a structural medium is provided for the transmission of the characters of the parents to their offspring, and the phenomena of heredity may be said to rest on a physical basis.

The material which forms the structure of the male and female pronuclei and the segmentation-nucleus has been termed by Weismann the *germ-plasm*. He believes that in each individual produced by sexual generation, a portion of the germ-plasm derived from both parents is not employed in the construction of the nuclei of the cells and tissues of the soma or personal structure of the individual, but is set aside unchanged for the formation of the germ-cells of the succeeding generation. According

to this theory there is a direct continuity of germ-plasm from one generation to another, which acts as the conveyor of hereditary characters. Weismann maintains that the germ-plasm is not modified by the habits and mode of life of the individual, and he conceives it to be transmitted from one generation to another uninfluenced by the conditions of life in which the individual is placed. He assumes that the reproductive cells which contain the germ-plasm are not acted on by the organs and tissues of the body in which they are situated, except in so far as they may be affected by general conditions of growth and nutrition. Hence, he concludes that characters acquired by individuals during their lifetime from any external cause, which modify the persona or soma, cannot be transmitted to their offspring.

Several arguments may, however, be advanced in opposition to Weismann's conclusion, which seems to require for its confirmation that the germ-plasm of the reproductive cells should, from the commencement of the development of the embryo, be isolated from the cells from which the other organs of the body are derived. But both reproductive cells and somatic cells are formed in the fertilised ovum by the segmentation of the nucleus, and the reproductive cells in man and other vertebrates do not appear as isolated organs until after the rudiments of all the great organic systems have been mapped out. Hence, before they are set aside as germ-cells or sperm-cells, the germ-plasm has apparently been in a stage of diffusion, and under precisely the same influences as those which in the embryo affect the formative cells of the body generally, so that the conditions which would secure the germ-plasm and the somatic cells from mutual interaction are not complied with.

Further, there is experimental evidence to show that in placental mammals an interchange of material takes place during gestation in opposite directions from foetus to mother, as well as from mother to foetus. A character derived by a foetus by descent from its male parent may thus be acquired by the mother from the foetus, and influence the germ-plasm of her reproductive cells so as to be transmitted to her future offspring, even though they may not have the same male parent. Hence, it is an axiom with those engaged in the breeding of particular kinds of stock, that, if they wish to keep the strain pure, the mother must not at any time be allowed to beget offspring by sires of another blood.

The hereditary transmission of characters from parents to offspring is not limited to such as are normal and physiological, and of service in the perpetuation of the species and of the race. Characters which are of no service, and, indeed, are detrimental to the individuals in whom they occur, may also be transmitted, and it is from this point of view that the subject of Heredity requires to be considered in this place. The study of those modifications in the structure of the body, which pathologists group together under the name of Congenital Malformations, has furnished numerous illustrations of the descent in families of variations from the normal structure. Familiar examples are furnished in the presence of supernumerary digits on the hands or feet in some families, or a diminution in their number in others. But modifications or variations in structure that can be transmitted from parents to offspring are by no means limited to changes which can be recog-

nised by the naked eye. They are sometimes so minute as to be determined rather by the modifications which they occasion in the functions of an organ than by the ready recognition of structural variations. One might adduce as an example Daltonism, or colour-blindness, which has distinctly been shown to be hereditary, and which is due apparently to a minute structural defect in the development of the retina, or the optic nerve, or the brain itself, occurring in particular families.

But there are certain diseases which occur in some families more than in others, and which are regarded as hereditary. Thus there is a strong tendency to the production of cataract in successive generations, and in other families an equally strong predisposition to the hæmorrhagic diathesis. When we speak of tendencies, susceptibilities, proclivities, or predisposition to the transmission of characters, whether they be those of health or of disease, we employ terms which undoubtedly have a certain vagueness. We are quite unable to recognise, even with the highest powers of the microscope, any structural difference in the germ-plasm in different persons which would enable us to say that in one family a particular feature should have one form, in another family a different form; or that in one family there should be a tendency or susceptibility to one kind of disease, while another family should display a special capacity for transmitting another form of disease. We can only determine that such a sequence will take place by tracing the life-history of the individuals belonging to these families. Though, as we have said, these terms have a certain vagueness, and are wanting in scientific precision, yet it is not the less true that they express a something of the importance of which we are all conscious, though we may not be able to formulate it in a precise definition. WILLIAM TURNER.

HERMAPHRODITE (*Ἑρμῆς*, Mercury; and, *Ἀρροδῖτη*, Venus).—A term applied to an individual in whom the formation of the sexual organs is such as to give rise to the impression that both the male and the female organs are present. See MONSTROSITIES.

HERNIA (*hernia*, a rupture).—SYNON. : Fr. *Hernie*; Ger. *Bruch*.

DEFINITION.—By a hernia is meant the protrusion of an organ from the cavity in which it is normally confined. The intestine is the part which most commonly suffers from this form of displacement, and consequently the term 'hernia,' without any qualifying epithet, usually means protrusion of some part of the gut from the abdominal cavity, and is equivalent to the popular expression 'a rupture.' Other organs to which the term is applied are the brain (*hernia cerebri*), the lung (*hernia pulmonis*), and the testicle (*hernia testis*). All the abdominal organs, with the exception of the pancreas, have at one time or another been found among the contents of hernial protrusions. In the present article the forms of hernia to which the abdominal viscera are liable are alone considered.

CAUSATION.—In order to establish the treatment of hernia on a scientific basis, it is necessary to study the mechanical factors that are responsible for its production. The form of the abdomen remains normal only so long as there is a proper relationship between the intra-abdominal tension and the resistance offered by the abdominal wall. If the

intra-abdominal tension be increased to an extent beyond that which can be borne by the muscular and tendinous surroundings, a protrusion of a portion of the contents results in the situation of least resistance. For instance, in infancy the intra-abdominal tension may be rendered excessive by the presence of gas in the intestines resulting from indigestion. In addition to the gas there is often present a variable quantity of fluid in the peritoneal cavity resulting from the same cause. This produces in the young infant a general distension of the abdominal wall, and a progressive yielding of the recently cicatrised umbilicus, forming an umbilical hernia. Fluid and bowel may be forced singly or together into the inguinal canal forming inguinal hernia or hydrocele in the male or female. A distinct ventral hernia may occasionally result from the same cause, the fibrous tissues between the recti muscles yielding under great strain. Later, in vigorous life, the intra-abdominal tension may be raised to such a pitch by the violent contraction of the abdominal wall that some of the viscera may be driven along the inguinal canal, the escaping structures gradually acquiring a peritoneal covering or occupying a still unobliterated process of peritoneum. This may occur suddenly, as in lifting a heavy weight, or in a violent effort of coughing, or straining to expel feces; or it may result gradually from a succession of such efforts. On this account certain occupations render the labourer particularly liable to this accident. Later in life the intra-abdominal tension may be greatly increased by the abundant formation of fat in and about the viscera, while the resisting-capacity of the wall is diminished in a corresponding manner by its deposit in and between the muscular planes.

In the female intra-abdominal tension is increased very rapidly by the pregnant uterus or by tumours in connection with the ovary and uterus. In this sex the inguinal canal is much more secure than in the male, while the femoral canal is much less so.

The resisting power of a portion of the abdominal wall may be reduced by some injury to it, such as an incision, and the resulting cicatrix may yield under the strain to which it is habitually exposed.

In considering the treatment of any variety of hernia the surgeon must therefore consider how he can best reduce the intra-abdominal tension, and how he can most effectually restore to the abdominal wall its original integrity and resisting-power. A hernia may have existed for so long that, to effect a cure, recourse must be had to operative interference in order to restore to the defective portion of the abdominal wall its normal structure and formation. Even after this has been effected satisfactorily the surgeon must see that the same mechanical conditions which originally produced the rupture do not continue to exist after his operation; or if they must still do so, as in the labourer, chronic bronchitic, &c., he should supplement the resisting-capacity of the abdominal wall by means of an efficient support or truss.

In the case of a hernia the contents of which can be reduced within the abdominal cavity, it is necessary not only to adopt such measures as will tend to reduce the intra-abdominal tension and increase the resisting-power of the abdominal walls, but also to maintain such constant pressure upon the aperture of exit from the abdomen, or to place opposite it such a rigid resistance, as will effectually prevent any subsequent escape of the abdominal

contents through it. The sac and its coverings exist only as long as the pressure which the intestines exert upon them continues in action. On removing this pressure by preventing the escape of the intra-abdominal contents, the sac gradually shrinks up and disappears. It is usually supposed that such a change only takes place during early life, and few surgeons expect to effect what is called the 'cure' of a hernia in an adult; indeed, it is usual to order that the truss be removed at night when the patient adopts the recumbent posture, and that it be replaced before the erect posture is resumed. This is wrong both in principle and in fact. The great difficulty that the surgeon experiences in the treatment of hernia is in obtaining a properly fitting and efficient truss. The time and skill required for the manufacture and perfect fitting of a truss are considerable, and the latter is particularly difficult to obtain. Again, the circumstances and surroundings of the patient are frequently such that it is impossible to count on the bowel being retained permanently within the abdomen, and in such cases a so-called 'radical cure' should be performed. In the case of umbilical and femoral hernia excision of the sac or more or less complete closure of the aperture of communication is effected. No cure of an inguinal hernia in the male can be properly called 'radical,' since a channel which is occupied by the spermatic cord must of necessity be left. The only real form of radical cure of inguinal hernia is that associated with the removal of the testicle and the complete closure of the external abdominal ring.

Classification.—The most practical classification of hernial protrusions is based upon the usual division of the abdomen into three regions, namely, the epigastrium, mesogastrium, and hypogastrium.

1. Protrusions in the epigastric region are very rare. They are (a) *diaphragmatic* and (b) *epigastric*.

(a) *Diaphragmatic* hernia is due either to relaxation or to laceration of the muscular tissue of the diaphragm. In some cases congenital deficiency of the muscle is the primary cause; in others the natural openings in it become dilated. Signs of this hernia are very obscure, but when the protrusion depends upon the laceration of the muscle, the occurrence of a recent injury may excite suspicion, if associated with abnormal physical signs in the thorax.

(b) *Epigastric* hernia escapes at the region bounded by the cartilages of the false ribs on either side of the linea alba. It is very rare, and, as the abdominal orifice of the sac is usually large, the hernia is easily reduced.

2. The hernie in the mesogastrium are (a) *ventral*, (b) *umbilical*, and (c) *lumbar*.

(a) The term *ventral* is given to any hernial protrusions escaping through abnormal openings in the walls of the abdomen to which no special name is given. They are seen in the region of the linea alba, either above the umbilicus, or, more frequently, below it; in the line of the linea semilunaris; and even over the muscular portions of the walls. Commonly of traumatic origin, their nature is clearly shown by the ready manner in which the protruded viscus can be pressed back into the abdomen. They sometimes ensue upon the weakening of the walls after distension, or upon the loss of tissue following an abscess.

(b) *Umbilical* hernia is met with at all ages and

in both sexes. It forms a tumour at the site of the umbilicus in the first instance, and gradually descends over the linea alba as its bulk increases. Very soon after birth this variety of hernia appears. The protrusion takes place at the umbilical ring, and as it pushes the peritoneum before it, an acquired hernial sac is formed. To prevent, therefore, the development of the sac in infancy, and to assist the closure of the ring in the linea alba, a slightly convex disc of cork, enclosed in washleather, should be strapped over the umbilical aperture. The prognosis of infantile umbilical hernia is favourable, for the aperture closes with age, and the tissues continue firm.

In adult life this kind of hernia is frequent in fat individuals. The tumour often acquires enormous proportions. Its contents consist of small intestine and omentum, with not uncommonly a portion of the transverse colon. Accumulations of fecal matter therein often give rise to obstruction, and the symptoms arising in consequence of this state more or less resemble those of strangulated small intestine. A correct diagnosis of the condition may usually, however, be arrived at from the history of the attack, the comparative mildness of the malady, and the prompt alleviation of the symptoms produced by exciting an action of the bowels. The contents of this form of hernia, when of long standing, often become adherent or bound by bands to the sac, in which state they remain permanently irreducible.

When the protruded viscus can be entirely reduced within the abdominal cavity, a suitable well-fitting truss should be worn constantly; if irreducible, one adapted to the circumstances of the case must be used.

(c) *Lumbar* hernia takes place in the loins. It is a very rare variety, and usually occurs as the result of an injury.

3. The hernie in the hypogastrium are the most numerous and the most common. They include: (a) *inguino-scrotal* or *inguino-labial*, above Poupart's ligament; (b) *femoral*, below Poupart's ligament; (c) protrusions through the apertures of the pelvis in front, beneath the horizontal ramus of the pubes—*obturator*; (d) beneath the arch of the pubes—*perineal*, *puddental*, *vaginal*; and (e) behind, through the ischiatic notch—*ischiatic*.

(a) *Inguinal* hernia is seen at all ages and in both sexes. The following varieties are described: the *oblique* or *external*; and the *direct* or *internal*. In the first, the orifice of the sac is external to the course of the internal epigastric artery; in the second it is internal to this vessel. When the protrusion forming an inguinal hernia does not descend below the inguinal canal it is termed a *bubonocoele*; but when it occupies the scrotum or labium it forms an *inguino-scrotal* or *inguino-labial* hernia. The essential difference between the inguinal hernia of youth and that of middle age lies in the constitution of the sac which encloses the protrusion. From infancy to early adult life, protruding viscera escape from the abdomen into a serous sheath continuous with the parietal peritoneum, namely, the vaginal process of that membrane which extends into the scrotum or labium. In middle life and afterwards, the parietal peritoneum is thrust through apertures or weak points in the abdominal walls by the protruding viscus. In this way two distinct kinds of hernial sac are formed, the first being due to a congenital defect, the second

to a mechanical and acquired cause. In practice, it is very important to bear these distinctions in mind. In the first kind a truss is applied to prevent the passage of the viscus into the sheath, in the hope that by this means its walls may unite and its orifice contract—in fact, to assist nature in accomplishing that condition, the failure of which permits the protrusion to take place. But, in the second, a truss is used to prevent the protruding viscus pushing the peritoneum before it, and so forming for itself a sac; if the development of the sac be thus arrested, there can be no hernial protrusion.

Inguinal herniæ occupy the inguinal canal, and are therefore in relation with the spermatic cord in the male, and the round ligament in the female. They escape from the canal through the external abdominal ring into the scrotum or labium. The neck of the tumour is, therefore, always above Poupart's ligament, and to the inner side of the external pillar of the external abdominal ring. This anatomical fact constitutes the main distinction between inguinal and femoral hernia.

(b) *Femoral* hernia forms a tumour at the inner and upper part of the thigh, immediately below the pubic attachments of Poupart's ligament. These structures are in immediate relation with the neck of the sac. The protrusion escapes at the femoral aperture, the site of the entrance of the lymphatic vessels of the thigh into the abdominal cavity. The neck of the sac is, therefore, to the inner side of the sheath of the femoral vessels; although, in proportion to the bulk of the tumour, its body may overlies it, and even extend upwards above Poupart's ligament, and outwards towards the crest of the ilium. The sac of a femoral hernia is always an acquired formation: hence arises the importance of wearing a truss after observing the slightest indication of a femoral protrusion; for if the yielding, relaxed parietal peritoneum be supported at the crural aperture by a well-adjusted pad, a visceral hernia must be avoided, as there will be no sac into which it can escape. In other words, arrest the development of the sac and there can be no hernia.

To discriminate between a femoral and an inguinal hernia, place the index-finger upon the spinous process of the pubes; if the neck of the tumour is to its outer side, and the whole length of Poupart's ligament can be traced above it, a femoral hernia exists; should precisely the reverse conditions be ascertained, the tumour will be due to an inguinal protrusion. Another method of diagnosis is the direct and careful examination of the site of the femoral aperture: if it is clearly and distinctly tangible and well-defined, it cannot be occupied by a hernial protrusion.

Femoral hernia is most common in the adult female. It has been developed before ten years of age; is rare between that age and twenty; but is very frequent in persons between twenty and forty years old. Prolific women are more frequently the subjects of this hernia than the single and sterile.

(c) *Obturator* hernia escapes from the pelvis through the thyroid foramen, and traverses the canal normally occupied by the obturator nerve and vessels. It is rarely met with. A fulness, rather than a tumour, is produced at the inner or pubic region of the thigh, beneath the pectineus muscle, accompanied by a peculiar numbness and pain, which may be traced to the distribution of the filaments of the obturator nerve. The lives of patients have been lost in consequence of overlooking these

herniæ, the cause of death being only ascertained *post mortem*.

(d) *Perineal*, *puddental*, *vaginal*, and (e) *ischiatric* herniæ are very rarely seen. The name assigned to each indicates the locality in which the tumour is formed; and for a special description of them the reader must be referred to monographs on the subject of this article.

RESULTS AND TREATMENT.—We must next, as briefly as possible, describe generally the various morbid conditions which the hernia itself may undergo, and the means by which serious consequences arising from such conditions may be averted.

All hernial protrusions are either *reducible* or *irreducible*—that is, they can either be restored to their normal situation, or they are permanently confined to the region in which they are protruded. The treatment of all reducible herniæ consists in the employment of means to prevent the escape of the protrusion. To effect this object various kinds of bandages or *trusses* have been devised. Each kind of hernia requires its special form of truss, and every individual should, as far as practicable, obtain a truss well fitted to his or her configuration. The essentials of a good truss consist in the spring having sufficient power to support the hernia and prevent its escape, while it should not be so strong as to injure the structures about the abdominal rings. The pad should be firm, of a shape suitable to the case, and of a size not inconvenient to the wearer. In ordering a truss the practitioner should bear in mind that it is necessary to state the circumference of the body two inches below the iliac crests, with the measuring tape so arranged that it lies over the seat of the hernia. Details as to whether the hernia is right, left, or double, and an accurate description of the size of the tumour should be supplied. Further, it should be stated whether it is of the femoral, scrotal, or inguinal variety, and instructions should be sent specifying whether strong, medium, or weak pressure is required.

The irreducibility of a hernia depends on its bulk, adhesions, and special anatomical conditions. Under such circumstances special bandages must be employed.

But other much more important morbid states of the protruded viscus than the above cause impediments to the reduction of a hernia, namely: (1) *constriction* by the tissues around the orifice of the sac; (2) *accumulation* of fecal matter in the protruded viscus; (3) *inflammation* of the hernia; and (4) *strangulation*, when a part of the alimentary canal forms the hernia.

1. Those herniæ, for example the inguinal, which pass through openings in the muscular walls of the abdomen, are liable to *constriction* from contraction of the muscular tissue. Inguinal herniæ of long standing and more than ordinary bulk are very prone to become irreducible in consequence of muscular contraction. If the patient be placed under the full influence of chloroform, the abdominal muscles become relaxed, and the hernia is quickly reduced.

2. Hernial protrusions formed of large intestine, such as occur at the umbilicus, frequently become irreducible from *fecal accumulations*. In these cases enemata, and even purgative medicines cautiously prescribed, frequently relieve the symptoms.

3. *Inflammation* excited in an omental protrusion may cause temporary and even permanent irreducibility. Local and constitutional symptoms of a

rather severe type sometimes attend such cases. The usual methods adopted to induce resolution must be employed.

4. A hernia is described as *strangulated* when subject to a constriction which at first impedes, and sooner or later arrests, the circulation of the blood in its capillary vessels. The passage of the intestinal contents is necessarily stopped. A patient the subject of this state remains in the greatest danger to life so long as the exciting cause, the constriction of the bowel, exists. Hour by hour that danger increases; and, although rare instances of recovery might be quoted after the continuance of strangulation for many hours, the majority of patients die because the intestine was not liberated early enough. The local and constitutional symptoms are strikingly characteristic. Very frequently the first symptom is vomiting, unaccompanied by any alvine evacuation. The vomiting continues, and is excited by ingesta. This state is probably due to mere obstruction of the alimentary canal, but it ought always to excite the anxious solicitude of the medical attendant to ascertain whether the patient has any outward signs of a hernial tumour. He must examine those regions at which protrusions commonly occur, and never rest content with the statements of the sufferer. At first the pulse is not affected in a very marked way, but as vomiting continues the heart beats more rapidly, while the pulse becomes weaker and contracted. The surface, especially that of the extremities, becomes cold; the countenance aged and anxious; the visage, lips, and hands shrivelled and bluish; the prostration extreme. The tumour is painful when touched, and it may have increased in size and become tense. All these facts indicate progressive morbid changes in the tissues of the strangulated bowel, as well as in that part of the alimentary canal above the hernia. Besides the mere act of vomiting all ingesta, the characters of the fluid vomited must be carefully noted. Usually, at first, it is the food last swallowed, more or less digested and mingled with bile; in the second stage it becomes yellowish or greenish, and at last it is stercoraceous—that is, offensive to smell, of a brownish colour and frothy, and often in great quantity.

To understand the pathological phenomena which may occur in strangulated hernia, it must be remembered that a hernia may be developed on a single occasion, and this is especially the case when bowel is driven into an unobliterated vaginal process. But more commonly the production of a 'rupture' is a gradual one, the bowel entering the canal and proceeding along it, and finally passing out through the external abdominal ring into the scrotum. In either of these circumstances the contents of the hernia, whether bowel or omentum or both, are liable to become strangulated, and the mode in which the bowel reacts to the strangulation varies in a marked manner in the two conditions. The variation depends on the character of the constriction. In a hernia into the unobliterated peritoneal process, the constriction results from the presence of a sharp hard diaphragm, which corresponds to the position of the internal abdominal ring, and represents the mode in which the vaginal process of peritoneum is being normally obliterated at this point. In the slowly acquired variety, the constricting medium usually corresponds to the junction of the sac with the abdominal cavity, called the neck of the sac, and is broad and smooth. In the case of

the sharp constriction, the period of congestion of the strangulated knuckle consequent on the interference with the backflow of blood from it is brief, for the reason that the mucous and muscular coats of the bowel become thinned by the pressure of the sharp peritoneal edge upon them, and in this way a space is provided which allows the passage of blood along the veins. The mucous and muscular coats ulcerate rapidly along the line of compression, and nothing but the peritoneal coat which readily perforates may remain, while the appearance of the loop of bowel enclosed in the sac may present no abnormal degree of congestion. In such cases the operator should be careful to withdraw the bowel from the abdomen for a sufficient distance to enable him to examine the line of constriction, and if he finds the muscular and mucous coats destroyed to a dangerous extent he can invaginate the line of ulceration by a series of Lembert's sutures. On the other hand, when the constriction is broad the obstacle to the backflow of blood not only does not diminish, but is steadily increased, owing to the engorgement and inflammation of the strangulated portion. Such a loop presents quite a different appearance from the former, being swollen, thick, and leathery, and most livid at the portion furthest from the constriction. The bowel at the seat of strangulation presents no such ulcerative changes as those just described, but looks fairly normal, its nutrition being hardly if at all impaired by the pressure it has been subjected to. In this condition, if the engorgement be excessive, the whole loop must be excised, and continuity of the bowel above and below the constriction established by whatever means the operator prefers. The only treatment of these urgent symptoms consists in the liberation of the bowel by surgical means. In the meantime palliatives may be employed, opium administered by the mouth, enemata injected, local applications of ice used, and gentle taxis applied.

The surgical treatment of strangulated hernia resolves itself into two methods—taxis and operation. *Taxis* is the term applied to the judicious application of external pressure to the contents of the hernial sac for the purpose of returning the tumour into the abdomen. Taxis undoubtedly may obviate operation, and therefore should be considered as a first method of treatment in these cases; the practitioner, however, should always remember that an essential condition in the performance of taxis is that it should be done with the utmost gentleness, otherwise there is a very serious danger of the wall of the bowel being injured and bruised with subsequent inflammation. It has been advised that the following positions should be observed in performing taxis. The pelvis should be elevated and the thighs flexed in inguinal hernia; the thighs should be flexed and slightly rotated inward in femoral hernia; and in umbilical hernia the legs should be drawn up for the purpose of relaxing the muscles of the abdominal wall. Some success has been achieved by applying one teaspoonful of ether over the hernial tumour every twenty minutes, covering with compresses during the interval; after about three applications or even less, the tumour loses its tightness, diminishes in size, and may slip spontaneously into the abdominal cavity. It is important that the parts around the tumour should be well protected by copious smearing with olive oil. Taxis should not be undertaken if there are any signs of inflammation of the superficial tissue; where taxis has been

attempted before ; where the condition has lasted for many hours ; or where it is possible that intestinal gangrene has been set up. In those cases in which reduction of the tumour has been successfully accomplished by means of taxis, but no alleviation of the symptoms has been produced, then among other possibilities the question whether what is called 'reduction *en masse*' has occurred must be taken into consideration. Three chief forms of this accident have been described : (1) where rupture of the sac has occurred through which the contents have been forced ; (2) where the strangulated bowel has been reduced into a loculus of a bilocular sac ; (3) where the sac itself with the contained strangulated bowel has been returned into the abdominal cavity. The only safe means of arriving at a definite conclusion under these circumstances is an exploratory operation.

The desirability or otherwise of giving a general anæsthetic in the treatment of strangulated hernia by taxis must be decided after consideration of the facts in each individual case, but it should be clearly arranged before the patient is rendered unconscious that operative interference should be undertaken in case the effort to return the strangulated bowel into the abdominal cavity is ineffectual.

W. ARBUTHNOT LANE.

HERNIA CEREBRI.—See SKULL, Diseases and Deformities of.

HERPES FACIALIS.—SYNON.: Herpesfebrilis ; Herpes labialis.

The term herpes facialis is applied to a small group, or groups, of vesicles on a red base. The eruption is associated with some swelling of the skin or mucous membrane, and with a sensation of very slight pain and stiffness of the part affected. It is most commonly met with on the lips, but occasionally on the alæ of the nose, the ear, or the cheek. It is also not uncommon on the buccal mucous membrane, and on that of the soft palate and uvula. It is generally, but by no means always, confined to one side, and this is more observable on the face or ear than on the lips, where it often extends to both sides of the middle line. The eruption is frequently associated with catarrh of the air-passages, and, though quite unimportant, is apt to recur. No treatment is required, as the eruption disappears in a few days.

ROBERT LIVEING.

HERPES PROGENITALIS.—This disease differs but little from herpes facialis except in the part affected ; it is, however, very apt to be troublesome, especially when irritated by rubbing or injudicious treatment. The eruption is met with in both sexes, but is more common in the male than in the female. In men it appears on the prepuce or glans penis ; in women on the labia or adjacent mucous membrane. When irritated, it is apt to form small ulcers, which are difficult to heal, and which lead to enlargement of the inguinal glands. Under these circumstances herpes has often been mistaken for syphilis.

TREATMENT.—This should be always of the most soothing kind, such as the application of water dressing or a very weak boric acid or lead lotion, with mild aperients.

ROBERT LIVEING.

HERPES ZOSTER (ἑρπας, I creep ; ζωστήρ, a girdle). SYNON.: Zona ; Shingles ; Fr. *Dartre* ; Ger. *Herpes* ; *Bläschenflechte*.

DEFINITION.—An acute vesicular eruption running round one half of the body, following a course determined by the structure of the nervous system and not by that of the skin.

ÆTIOLOGY.—Both sexes are equally liable to the disease. It most commonly occurs between the ages of three and twenty, with a greater proneness to appear between four and thirteen. Children below one year of age are not commonly attacked, but a case has been recorded in an infant four days old. The aged are usually supposed to be more liable to the disease, but this belief probably arises from the extreme severity of the disease in old and debilitated persons, and the intensity of the pain which it frequently leaves behind it.

In the majority of cases zoster arises without known cause. Cold is sometimes invoked to explain its origin. Like other acute specific diseases it begins suddenly with more or less fever, and after a variable period the characteristic lesion appears. It runs a definite course, tends to occur in epidemics, and second attacks are rare. Although persons apparently in perfect health are frequently attacked, those whose resistance is weakened by some intercurrent disease are more prone to suffer from zoster. Thus many of the children attacked have recently suffered from whooping-cough, measles, diarrhoea, or some similar ailment. Pregnant women are especially susceptible, and zoster may follow operations on the pelvic organs. Phthisis is also a well-marked predisposing factor. Patients who are taking arsenic also seem to be more prone to herpes. Attacks of zoster are frequently attributed to mental causes, such as fear or sorrow ; but these influences would appear to act, if they act at all, only by rendering the patient more prone to attack.

Diseases of the nervous system undoubtedly render the patient more liable to herpes zoster. Thus it is extremely common in general paralysis of the insane. But in some nervous diseases zoster is apparently a direct symptom of the pathological changes that underlie the disease. This is the case in myelitis, spinal caries, pachymeningitis, cerebrospinal meningitis, and tabes dorsalis. In all these affections zoster may arise in consequence of implication of the posterior root-ganglion in the morbid process. In such cases the eruption is best spoken of as 'symptomatic,' as opposed to 'spontaneous' zoster.

MORBID ANATOMY.—A vesicle of zoster at its height is a unilocular cavity, the floor of which consists of naked papillæ. Incomplete partitions are formed by altered epithelial cells which retain their attachment to the roof of the vesicle. The cavity is filled with swollen epithelial cells of all ages which have lost their prickles, and with leucocytes ; occasionally certain protozoa-like bodies are seen, which have been shown to be formed from altered epithelial cells. The papillæ beneath the vesicle are filled with small round inflammatory cells, and their vessels are engorged. If death takes place in the acute stage, one of the posterior root-ganglia will be found to be intensely inflamed. The vessels will be engorged, and hæmorrhage will probably have occurred into the substance of the ganglion at one or more spots. Should the lesion be severe and death take place at a later stage, the affected area in the ganglion is found to be converted into dense fibrous tissue, in which neither nerve-cells nor nerve-fibres can be seen.

SYMPTOMS.—The onset of the rash is frequently

preceded by slight malaise, especially in children. The child lies about by day and tosses restlessly at night. It may vomit or refuse food. Adults may suffer from shivering similar to that which accompanies the onset of acute lobar pneumonia, but of less intensity. During this period the temperature is generally raised somewhat; in adults as a rule it does not exceed 100°F. , but in children it may occasionally reach 102°F. Pain is usually present from the first: it is shooting in character, and worse at night. It occupies the area subsequently covered by the eruption. With the appearance of the rash the temperature usually falls, while the pain remains; but this is by no means always the case. Thus, the rise of temperature lasts from three to five days, and this period may be considered the duration of the acute disease. The rash, on the other hand, may either begin to make its appearance a few hours after the onset of the attack or may be delayed until the acute general symptoms are past. Most commonly it begins to appear about the third or fourth day of the illness. If it comes out early it does not usually reach its full extent for two or three days, whereas if it is delayed it may attain its full development in twelve hours.

It occupies areas on the trunk and limbs which represent the distribution of nerve-fibres that enter a single posterior root-ganglion. These areas are approximately shown in the figures illustrating the article on PAIN IN VISCERAL DISEASE.

From the time when the rash first makes its appearance it spreads with varying rapidity. In each affected area three spots usually exist at which the branches of the nerve come to the surface (the posterior primary, and the lateral and anterior branches of the anterior primary division). It is with these points as centres that the eruption first makes its appearance: from these it spreads along the distribution of the main branches, and may invade the territory supplied by even the finest nerve-twigs, until the whole area is occupied by vesicles or raised erythema. The most severe incidence of the eruption always falls on the skin in the neighbourhood of the central points, and it is over these that, in the severest cases, huge bullæ or small gangrenous patches may appear. But the large majority of cases do not run so severe a course, and in some the whole eruption consists only of a few vesicles scattered around one or more of the maximum spots. On the palm and on the sole of the foot vesicles are rare, and, when present, tend to be of small size, very little raised and not surrounded by erythema. Vesicles on the fingers, the back of the hand, the toes, and the dorsum of the foot are not usually severe.

The rash may consist, from the first, of vesicles, containing clear fluid, surrounded by more or less erythema; but more commonly it first shows itself as an erythema upon which vesicles rapidly arise. In very severe cases the vesicles may contain blood-stained fluid. Sometimes these rapidly break down, giving place to shallow ulcers. In all such cases subsequent scarring is profound and much after-pain is likely to result. In most cases the contents of the clear vesicles become turbid, and, possibly in connection with this pus-formation, the lymphatic glands that drain the affected area of skin are usually enlarged and frequently somewhat tender. About the fifth to the tenth day after their first appearance the vesicles begin to dry up and form scabs. Under these scabs the eruption

heals, and at the end of six weeks nothing is to be seen beyond some freshly healed scars. If the eruption has been severe the scars may be large, irregular, and white, closely resembling those of a superficial burn.

During the period when the rash is fully out, the pain becomes more local. It may be little more than a painful itching or it may become of an agonising burning character. Usually the pain dies away when the rash begins to heal, but in elderly patients it may last for weeks, months, or even years after the scars are formed. This severe after-pain is relatively more common where zoster has affected the ophthalmic division of the trigeminal nerve, and is always associated with considerable scarring.

Second attacks are extremely rare, and in no recorded case has a second attack coincided in distribution with the first. Two simultaneous eruptions at different levels have been known to occur.

Zoster of the Head and Neck.—Within the territory of the first or ophthalmic division of the trigeminal nerve, zoster, exactly resembling in course that seen on the body, is a fairly common occurrence. The area occupied by the eruption may extend over the whole or part of the ophthalmic division of the nerve, and may involve the side of the nose as far as the upper border of the ala nasi. This implication of the side of the nose is of great importance, for it is in these cases that the eye is affected. The conjunctiva becomes red and injected, and ulcers may appear on the cornea. Iritis may also occur, and it is therefore always wise in these cases to keep the pupil well under the influence of atropine. Panophthalmitis resulting in loss of the eye has also been described.

Herpetic eruptions about the lips and nose or on the cheeks are common in febrile states, but such eruptions bear no relation to herpes zoster. They are usually bilateral, notoriously prone to recur, are not preceded or accompanied by neuralgic pain, and do not follow any definite nerve-course. But true zoster of the face occurs, and may be distributed over either the second or third division of the trigeminal nerve.

The tongue may also be the site of an herpetic eruption, but the vesicles rapidly break and give rise to shallow ulcers. These ulcers are usually found on the upper surface and tip of the tongue. This form of eruption is probably more frequently a form of herpes febrilis than of true zoster.

COMPLICATIONS.—*Cutaneous.*—The rash usually heals and leaves scars within a few weeks; but occasionally gangrenous sores may appear and last for many weeks or even months. The eruption seems to be quite uninfluenced by the simultaneous existence of other cutaneous lesions. Thus it is not uncommon in patients suffering from psoriasis, owing probably to the almost universal exhibition of arsenic in this disease, and in such cases it shows no deviation from its usual course and distribution.

Motor.—Occasionally, though rarely, zoster is accompanied by motor paralysis. Thus zoster of the areas of the arm may be associated with temporary weakness of the whole arm or of the hand, and that of the cervical areas may be accompanied by facial paralysis of the usual peripheral type. Ptosis and ophthalmoplegia externa and interna may be associated symptoms of zoster appearing in the distribution of the ophthalmic division of the trigeminal nerve.

TREATMENT.—No treatment is effectual in aborting the eruption, but when the rash has appeared it may be dusted with a powder consisting of starch (ζij), oxide of zinc (ζj), and camphor-powder (gr. 15 to 45); to these may be added, if there is much pain, gr. 15 of powdered opium. If preferred, an ointment may be applied consisting of boric-acid ointment (ζj) and cocaine (gr. 5).

For the after-pain no treatment but morphine is really effectual. It is, however, always well to try phenazone in 10-grain doses three times a day. General tonics, such as arsenic and quinine, are indicated; for patients who suffer severely from this after-pain are always debilitated.

HENRY HEAD.

HETEROLOGOUS (ἕτερος, other; and λόγος, nature).—A word used to characterise any morbid product, whether fluid or solid, which is different in composition or structure from the normal fluids or solids of the body.

HETEROMORPHOUS (ἕτερος, other; and μορφή, form).—Applied to new-formations which are different in form and structure from the normal tissues.

HETEROTOPOUS (ἕτερος, other; and τόπος, a place). Misplaced. A term applied to the appearance either of a normal tissue in an unnatural situation—for example, of hairs on mucous surfaces; or of morbid growths in unusual places—for instance, of epithelioma in nervous tissue.

HICCUP or HICCOUGH.—SYNON.: *Singultus*; Fr. *Hoquet*; Ger. *der Schlucken*.

DESCRIPTION.—Hiccup, according to physiologists, is a sudden spasmodic descent of the diaphragm accompanied by a spasmodic closure of the glottis, the characteristic noise being caused by the incoming column of air striking against the partially closed glottis. The assumption of a spasmodic closure of the glottis in hiccup seems scarcely warrantable. Normally the descent of the diaphragm in each respiratory act is accompanied by a contraction of the posterior crico-arytenoid muscles, which causes an outward rotation of the arytenoid cartilages, and a dilatation of the glottic aperture. The diaphragmatic and the laryngeal acts keep time together, and in health the rhythm of sixteen or eighteen to the minute is maintained. If, however, the diaphragm give a sudden descending jerk irrespective of any respiratory need, as is the case in hiccup, and this jerk occur at a time when the dilators of the glottis are not acting, a noise will be produced by the rush of air through the insufficiently widened glottic aperture. It seems certainly possible to account for the noise of hiccup by the mere fact of the descent of the diaphragm occurring when the glottis is not properly open. The noise is not a constant phenomenon, and during an attack of hiccup it never occurs during ordinary inspiration, or without the spasmodic action of the diaphragm, although the latter phenomenon may occur without the former.

ÆTIOLOGY AND DIAGNOSIS.—Hiccup may be produced by any irritation of the phrenic nerve—its origin, its course, or the ultimate twigs which are distributed to the under-surface of the diaphragm. Undue distension of the stomach, by being overfilled with food or drink, or by an accumulation of wind due to faulty digestion, is the most common cause of hiccup. Its occurrence from

this cause is far more common in children than in adults. Convulsions and muscular spasms generally are more easily caused in the young, and hiccup in this respect follows the ordinary rule. Hiccup is produced by direct or by reflex irritation. With many persons the introduction of hot spiced or peppery foods into the stomach immediately produces hiccup, and the writer knows one or two persons in whom hiccup is produced by the passage of hot fluids through the pharynx. It is a frequent symptom in peritonitis when the peritoneal covering of the diaphragm becomes affected. It sometimes occurs in cases of cancer of the stomach; occasionally, perhaps, from over-distension of the organ, but more often from an extension of the cancerous disease to the peritoneal surface of the stomach. It is occasionally a troublesome symptom during convalescence in cholera, and is often accompanied by eructations of wind, and sometimes by vomiting. If hiccup occur with any persistency in the course of typhoid fever, it is often an indication of perforation and the onset of general peritonitis. Although most frequently a symptom of gastric or abdominal disturbance, hiccup occasionally occurs as a true neurosis. It may accompany hydrocephalus or meningitis, and is then due probably to an implication of the cerebral origin of the phrenic nerve. It also occurs in uræmia and acute gout. Cases of obstinate hiccuping in hysterical subjects have been recorded, and certain cases of paroxysmal hiccup have been regarded as instances of modified epilepsy.

TREATMENT.—The treatment of hiccup will depend upon the cause. An emetic to empty the stomach, or a stimulant to increase its natural peristaltic action, will often give relief. If we can manage to produce a forcible action of the diaphragm, we may often succeed in curing it, as it were, of the trick of spasmodic action. Attempts to count a hundred without drawing breath, or to hold the breath for a minute, are familiar remedies for hiccup; and, by producing a feeling of suffocation, and necessitating a violent descent of the diaphragm, they are often successful. Warm applications or counter-irritation applied to the diaphragmatic region or over the cervical spine, may occasionally give relief. Pressure upon the trunk of the phrenic nerve, by means of the finger applied over the scalenus anticus muscle, is said also to have given relief occasionally in obstinate cases. Among the drugs which have been recommended for the relief of hiccup are chloroform (administered internally), either alone or combined with opium; camphor in the form of a spirit solution, in doses of twenty drops and upwards; valerianate of zinc, belladonna, bromide of potassium, trinitrin, musk, or antacids; and, in very severe cases, morphine administered hypodermically.

G. V. POORE.

HIDRADENITIS. — See SUDORIPAROUS GLANDS.

HIDROCYSTOMA. — See SUDORIPAROUS GLANDS.

HIPPURIA (ἵππος, a horse; and οὐρον, urine).—The condition of the urine in which it contains hippuric acid in excess. See URINE, Morbid Conditions of.

HIPPUS (ἵππος, a horse).—Rapid spasmodic variation in the size of the pupils apart from the action of light or of accommodation. See p. 630.

HISTRIONIC SPASM (*histrion*, an actor).—A synonym for facial spasm, so called on account of the contortions of the face to which this affection gives rise. *See* FACIAL SPASM.

HOARSENESS (Sax. *has*, having a rough voice).—Roughness of the voice, due to disease or disorder connected with the larynx. *See* VOICE, Disorders of.

HOBNAIL LIVER.—A name given to a cirrhotic liver, when it presents small prominences on its surface, somewhat resembling hobnails. *See* LIVER, Cirrhosis of.

HODGKIN'S DISEASE.—A synonym for lymphadenoma. *See* LYMPHADENOMA.

HOMBURG, in Germany.—Common salt waters. *See* MINERAL WATERS.

HOMICIDAL INSANITY.—*See* CRIME, Irresponsibility for; and INSANITY, Impulsive.

HOMOLOGOUS (*ὁμός*, like; and *λόγος*, relation).—In pathology this term is applied to new-growths presenting the same structure as normal tissues, such as fatty or fibrous tumours.

HOOPING-COUGH.—*See* WHOOPING-COUGH.

HORDEOLUM (*hordeum*, a barleycorn).—A synonym for sty. *See* STYE.

HORNS.—SYNON.: Cornu Cutaneum; Fr. *Corne de la peau*; Ger. *Hauthorn*.

DEFINITION.—Horns are circumscribed painless epidermic formations of irregular masses of keratin.

DESCRIPTION.—Horns are usually single, and rarely grow before the age of forty, though they have been met with in infancy. They vary in shape and size, being elongated, conical, curved, or twisted. They may grow on any part of the body, but are most commonly met with on the scalp, forehead, temples, and nose. Their surface is rugose, and they vary in colour, being either grey, brown, yellow, or black. In many instances horns arise from sebaceous cysts; they sometimes arise in warts (a horn may be regarded as an overgrown wart) and they may be the starting-point of a malignant growth. Unna regards them as papillary and medullated keratomata.

TREATMENT.—Radical treatment consists of excision of the horn including its base, so as to guard against its reproduction. If thought desirable, the latter may be dabbed with a solution of chloride of zinc.

HYDATIDS.—*See* ENTOZOA.

HYDATIDS, UTERINE.—*See* MOLE; MOLAR PREGNANCY.

HYDRÆMIA (*ὑδρᾱ*, water; and *αἷμα*, the blood). A watery condition of the blood. *See* ANÆMIA; and BLOOD, Morbid Conditions of.

HYDRAGOGUES (*ὑδρᾱ*, water; and *ἄγω*, I drive).—SYNON.: Fr. *Hydragogues*; Ger. *Wasser-treibende Mittel*.

DEFINITION.—Purgative medicines which cause a copious watery discharge.

ENUMERATION.—Hydragogue purgatives include:—Bitartrate of Potassium, Buckthorn, Colchicum, Colocynth, Croton Oil, Elaterin, Gamboge, Hellebore, Jalap, Podophyllum Resin, and Scammony. The two most important are Compound Jalap Powder and Elaterin.

ACTION.—It has been supposed by some writers that the action of the drugs included in the present class is due only to the increased peristaltic action which they produce. This, however, is not the case, as certainly some, if not all, of those just enumerated induce a free secretion of fluid by the intestinal mucous membrane, while at the same time they stimulate the peristaltic action of the bowel, and cause the evacuation of this watery fluid.

USES.—Hydragogues are chiefly employed for the removal of fluid from the body, in cases either of general anasarca or of dropsical effusion in serous cavities. They may be employed to assist the action of the kidneys when this is insufficient; and it has been observed not infrequently, when the secretion of urine has previously been deficient, that it becomes greatly increased after a free discharge of fluid has taken place from the bowels, in consequence of the administration of a hydragogue cathartic. *See* PURGATIVES.

T. LAUDER BRUNTON.

HYDRARGYRIASIS (*hydrargyrum*, mercury). The state produced by the introduction of mercury into the system. *See* MERCURY, Poisoning by.

HYDRARTHROSIS (*ὑδρᾱ*, water; and *ἄρθρον*, a joint).—Effusion of serous fluid into a joint. *See* JOINTS, Diseases of.

HYDROA.—SYNON.: *Dermatitis Herpetiformis*; *Pemphigus pruriginosus*; *Herpes gestationis*; *Herpes circinatus bullosus*.—This disease is characterised by a peculiarly polymorphic eruption. The type is erythematobullous, the vesicles, bullæ, or more rarely pustules tending to group, or be marginal, on the reddened area. Successive crops appear at irregular intervals for an indefinite period, the appearance of each being ushered in by an aggravation of the itching, a symptom always present to a certain degree, but diminishing on their full evolu-

tion. In distribution, partiality is evinced for the neighbourhood of the articulations, for the sacral region, and for covered parts generally, though the disease is not restricted to such. The herpetiform arrangement does not always prevail in the case of children, in whom the lesions may assume an isolated disposition.

COURSE.—Though occasionally acute in its inception, it runs an essentially chronic course as a rule, continual relapses taking place, or recurrences after a period of complete immunity. It is remarkable how well the health is maintained, when the extent of blistered and inflamed surface, and the restlessness due to the pruritus, are considered. The lesions are succeeded by crusts, which are hard and angular, and by stains and pigmentation; but permanent scars are rare. It may occur at all ages, may last many years, and while it usually terminates spontaneously, it may end fatally. The term *Herpes gestationis* has been given to it when, as sometimes happens, it appears during pregnancy or after delivery. Once having appeared, it is apt to reassert itself in subsequent pregnancies, though the sequence may not always be continuous. The vesicles are loculated and form in the substance of the rete mucosum, which is oedematous. They are firm and tense, arising between the cells, not within them, by ballooning, and the clear fluid with which they are filled contains a large percentage of eosinophile globules. No well-defined pathogenic microbe has been isolated by any method of culture hitherto tried. Peripharyngeal parenchymatous neuritis has been observed.

PATHOLOGY.—As to its pathology, the view is pretty widely held that the phenomena are due to toxins derived from absorption into the blood of excrementitious matters, or bodies arising from imperfect metabolism. These determine the cutaneous manifestations either directly or through the medium of the nervous system. There is often diminished excretion of urea preceding an outburst of the eruption, and it is believed that some toxic substance, normally eliminated in the urine, is retained in the blood. Though the toxin has not yet been identified, there are circumstances which go to support this view. Thus the administration of iodide of potassium at once intensifies the eruption, or induces an attack if latent. It is accepted that a bullous form of iodine-eruption, which much resembles it, is specially apt to appear when that drug is given in nephritis, or whenever the kidneys act inefficiently. A highly nitrogenous diet has seemed to accentuate the disease in some instances.

DIAGNOSIS.—To a superficial observer it most resembles *scabies*, but it exhibits no contagious properties; there are no burrows; the localisation is different; and the itching is not markedly worse at night. From *pemphigus vulgaris*, however, the distinction is not in all cases easy. Still in *pemphigus* there is hardly polymorphism, the bullæ are distributed irregularly, itchiness is only occasionally aggressive, while the constitutional symptoms are much more grave. Most instances of so-called urticaria bullosa, if not a mere accidental occurrence on some wheals, ought rightly to be regarded as dermatitis herpetiformis. *Erythema multiforme* is limited in duration, seldom itches, and bullæ are casual features. *Impetigo herpetiformis*, if not of pyæmic origin, may be a severe pustular eruption.

TREATMENT.—Arsenic exerts in most cases, though not invariably, a distinct controlling effect,

and during its administration the attacks are often abortive or less annoying. It should be pushed to the limits of tolerance, and persevered in for prolonged periods. Phenacetin has been suggested should arsenic fail. Pricking the blebs relieves the pruritus probably by diminishing tension. Painting the affected areas with a solution of ichthyol in water or calamine lotion in the proportion of one-sixth to one-fourth is most generally useful. Inunction with sulphur-ointment has also proved beneficial. Baths of permanganate of potassium are soothing, if not directly curative. The diet ought to include vegetables, farinaceous matter, and fish, but only a small quantity of meat. The action of the kidneys should be promoted by diluents or mild diuretics.

W. ALLAN JAMIESON.

HYDROCELE (ὕδωρ, water; and κήλη, a tumour).—**SYNON.**: Fr. *Hydrocele*; Ger. *Wasserbruch*.

DEFINITION.—A swelling produced by a collection of fluid in connection with (A) the testicle, or (B) the spermatic cord.

A. HYDROCELE OF THE TESTICLE.—The principal forms of hydrocele of the testicle are (1) *vaginal*, (2) *congenital*, and (3) the *encysted*; (4) *chylous*, (5) *bilobular*, and (6) *diverticular* hydrocele will also be noticed.

1. Vaginal Hydrocele.—**DESCRIPTION.**—This is a chronic dropsical effusion into the sac of the tunica vaginalis. The fluid is a pale-yellowish serum, which in old cases is often loaded with cholesterolin. The quantity varies, but seldom exceeds twenty ounces. As many as six quarts have been evacuated. The testicle is usually situated at the back part and rather below the centre of the sac; but its position may be altered by adhesions; and, in cases of congenital inversion, the testicle is in front of the sac. In old hydroceles the sac is often greatly thickened by deposition of lymph on the tunica vaginalis, and its conversion into fibrous tissue, which is sometimes the seat of calcareous deposits. Vaginal hydrocele is generally single, but often occurs on both sides. It forms an oval or pyriform swelling, which fluctuates; has a smooth, even surface; and commences at the lower part of the scrotum, very gradually and without pain. When examined by transmitted light it is found to be translucent, except at the back part, where the testicle is situated. Owing to the tunica vaginalis remaining unobliterated for some distance along the cord, the swelling occasionally assumes an elongated form, and extends up towards the inguinal canal. It is then known as *infantile hydrocele*. A hydrocele sometimes varies in size, becoming larger and more tense during the day than when the patient first rises in the morning.

ETIOLOGY.—Hydrocele is a common disease, especially in warm climates; and occurs at all periods of life, but is most common in middle age.

DIAGNOSIS.—The circumstances—that the swelling commences below; that the spermatic cord can be detected above the tumour; that the testicle cannot be felt; and that the tumour receives no impulse on coughing, and does not vary in size on pressure—are signs distinguishing a hydrocele from an inguinal rupture. When the sac is much thickened, so as to obscure fluctuation, and prevent the passage of rays of light, the tumour may be mistaken for a hæmatocele, or disease of the testicle, and the diagnosis is difficult.

TREATMENT.—In *Infants*, vaginal hydrocele generally disappears under the application of weak tincture of iodine or, as this may irritate the skin, of some evaporating lotion. Acupuncture, causing the fluid to escape into the areolar tissue of the scrotum, is the only operation that is required.

In the *adult* external remedies are of no use. It is usual to resort at once to operative treatment, *palliative* or *radical*. The *palliative* operation consists in puncturing the tumour with a trocar and cannula, and evacuating the fluid accumulated in the tunica vaginalis. The hydrocele usually returns in the course of two or three months, and then the operation must be repeated, or the patient must undergo *radical* treatment. This may be effected by incision or excision of the sac; or by injection of the sac with a stimulating fluid. The last is the plan most commonly resorted to, though an increasing number of surgeons now advocate primary excision on account of the liability to recurrence after iodine-injections.

The fluids which have been found most useful are: (1) the Edinburgh tincture of iodine; (2) a solution of perchloride of mercury—I grain to an ounce of water; and (3) carbolic acid and glycerin in varying proportions.

When iodine is to be used the patient should be placed in the recumbent posture, as faintness is not infrequent, and a sickening pain running up into the groin and lumbar regions is usually complained of. This may be avoided by injecting 10 m of a four-per-cent. solution of cocaine as soon as the hydrocele-fluid has been evacuated. A few minutes after the injection of the cocaine about a drachm of the solution of iodine is injected into the sac and there retained.

The injection of carbolic acid was introduced by Levis of Philadelphia, and is preferred by many surgeons, as being less painful and more efficient than iodine. Levis injects about a drachm of a solution composed of ʒj of carbolic-acid crystals, with the addition of 5 per cent. of glycerine or water. A sense of warmth is produced by the injection, which is quickly followed by a decided numbness, and the patient is at once able to walk about and to attend to his ordinary duties. No rest is necessary until inflammatory action sets in, which is usually after the lapse of twenty-four hours. It is said to be more certain in producing the necessary amount of inflammation for effecting a cure than iodine, and it appears to be less painful. One of the writers prefers the injection of a corrosive-sublimate solution, 1 in 500, as being more certain and less painful even than the carbolic acid. After the fluid in the sac has been withdrawn, an ounce or two of the solution is injected, and care is taken to ensure that it is brought into contact with every part of the serous sac before it is allowed to escape. To make quite sure that this is the case, the injection may be repeated. It will be noticed that when mercury is used it is simply as a wash, and is not left in, as is the case with both iodine and carbolic acid.

When employing the injection-treatment one precaution is especially necessary—the surgeon should see that the cannula has been passed well into the sac, or some of the fluid used as an injection may find its way into the areolar tissue through the slit (about half an inch long) in the side of the cannula. This accident was followed, in one instance of corrosive-sublimate injection, by salivation.

As a rule, after this method of treatment, no con-

finement to bed is necessary; but a suspensory bandage is advisable. A slight inflammation is set up in the sac, causing a rapid return of the swelling, which, however, gradually subsides until the patient is cured.

Sacs with thick walls are not suitable cases for the injection-treatment. Here excision is the proper treatment, though it must not be forgotten that even after the removal of the whole of the parietal layer of the serous membrane recurrence of the hydrocele has been recorded.

2. Congenital Hydrocele.—In children, the original communication between the cavities of the peritoneum and of the tunica vaginalis sometimes fails to be obliterated; and fluid accumulated in the sac constitutes the variety termed congenital hydrocele. The communication is usually small in size.

DIAGNOSIS.—Congenital hydrocele is easily distinguished from ordinary hydrocele by the absence of a defined boundary on the upper part of the tumour; by the impulse received on coughing; and by pressure causing the disappearance of the swelling, and rendering the testicle perceptible. It is distinguished from a reducible hernia by the fluctuation and transparency of the swelling; by the absence of gurgling accompanying its disappearance on pressure; and by the slow return of the swelling on the patient assuming the erect posture.

TREATMENT.—Congenital hydrocele is usually cured by the gentle pressure of a truss on the inguinal canal, so as to occasion obliteration of the neck of the sac, after which the fluid usually becomes absorbed. Should this fail, excision with ligature of the neck of the sac must be carried out.

3. Encysted Hydrocele.—In this form of hydrocele fluid is effused into an adventitious cyst distinct from the vaginal sac, developed in the areolar tissue beneath the visceral portion of the tunica vaginalis investing the head of the epididymis. There may be two or even more such cysts. As the cyst enlarges, the epididymis becomes flattened and displaced to one side, while the testicle is found either in front or at the bottom of the cyst. The fluid contained in the sac differs from that of vaginal hydrocele in being less in quantity, perfectly limpid and colourless, and nearly free from albumen. The fluid sometimes contains spermatozoa in great abundance, rendering it opaque and milky-looking. Their presence may be owing to the rupture of one of the tubes of the epididymis, and the escape of semen into the sac of the hydrocele. More probably, the spermatozoa-containing cysts are due to dilatation of one or more of the vasa efferentia in consequence of stricture; and those that contain limpid fluid may be developed from the organ of Giraldès.

DIAGNOSIS.—An encysted hydrocele is distinguished from vaginal hydrocele by the position of the testicle at the bottom of the tumour; and generally by the colourless character of the fluid evacuated.

TREATMENT.—When large in size, so as to be inconvenient, encysted hydrocele may be treated in the same way as vaginal hydrocele, and injection is attended with the same success.

4. Chylous Hydrocele.—**SYNON.** : Chylocele; Galactocoele; Liparocoele; *Fr. Hydrocèle laiteuse ou graisseuse.*

DESCRIPTION.—Chylous hydrocele may be bilateral or unilateral. It is not translucent, but it otherwise resembles an ordinary hydrocele. The

sease is one of the manifestations of the presence of the *Filaria sanguinis hominis*. See FILARIASIS.

TREATMENT.—Tapping is merely palliative, as the fluid soon re-accumulates. In one case, at the first tapping the fluid was of the ordinary serous nature, but this result appears to be unique. Injection with solution of iodine is usually successful. If it fail, incision, with drainage, or excision of the sac may be performed.

5. Bilobular Hydrocele.—SYNON.: *Hydrocele en bissac* (French surgeons).

DESCRIPTION.—This disease may be altogether outside, or partly inside and partly outside, the abdomen. The formation of the former variety is easily explicable. The *processus vaginalis* may be closed completely at the internal abdominal ring, and partially at its connection with the *tunica vaginalis propria*, the intervening part remaining open. In such a condition a hydrocele develop, it will form two sacs, continuous internally, and marked at their junction externally by a constriction, the depth of which will vary inversely with the size of the opening between the sacs. It will be a combination of a *funicular* and a *vaginal* hydrocele, with a communication between the sacs. The diagnosis cannot present any difficulty, and the symptoms, possible results, and treatment will not differ from those of an ordinary hydrocele of the *tunica vaginalis propria*.

For the formation of the other variety, where one sac is inside and the other outside the abdomen, two hypotheses are possible. It may result from some congenital malformation of the *processus vaginalis*, or this process may be closed at the internal abdominal ring, and, if a hydrocele subsequently develop, a diverticulum may be formed at the upper part of the process, and experience less resistance to its extension in the subperitoneal tissue than in the inguinal canal or the *tunica vaginalis communis*.

This form of bilobular hydrocele has been observed at birth, and the great majority of recorded cases have been in patients under forty years of age; but it may develop or become manifest at a later period. Some cases have been complicated with retention of the testicle within the abdomen or in the inguinal canal, but in others the gland has been in its normal position. The intra-abdominal sac may vary greatly in size. In one case it was not larger than a hazelnut; in another it extended above the level of the umbilicus and beyond the median line of the abdomen. It is usually situated between the peritoneum and the iliac fascia, but in one case it was between the peritoneum and the *fascia transversalis*. The external sac may also vary in size. Sometimes it is small, and limited to the *processus vaginalis*; but when the *tunica vaginalis propria* is also involved, the sac may be very large. When the contents of the sac are serous, the patient does not experience any greater inconvenience than with an ordinary hydrocele. But there appears to be in these cases a great tendency to the formation of a hæmatocele, and the intimate relation of the internal sac with the peritoneum may then become very important.

DIAGNOSIS.—When the intra-abdominal sac is large and causes a projection of the abdominal wall, attention cannot fail to be directed to it, and pressure over the abdominal swelling will produce increased tension of the external sac, and *vice versa*. But if the intra-abdominal sac be small, or lodged deeply in the iliac fossa, or extend into the pelvis,

it may escape notice; but the reducibility, partial or complete, of the contents of the external sac and the *immediate* re-appearance of the swelling when the pressure has been removed, ought to suggest the possibility of an intra-abdominal sac. Careful palpation, when the patient has been anaesthetised, will detect some fulness in the iliac fossa; and if the sac has extended into the pelvis, digital exploration through the rectum will aid the diagnosis.

TREATMENT.—The treatment will depend upon the size of the communication between the sacs, the nature of their contents, and their walls. If the communication be free, the contents serous, and the walls thin, tapping the external sac will empty the internal sac also, and the injection-treatment will probably effect a cure. But if the communication be very narrow, tortuous, or valvular, if extravasation of blood has occurred, or if the walls of the sacs be thick, operative treatment varying with the nature of the case will be requisite.

6. Diverticular Hydrocele.—This variety of hydrocele is also bilobular, but is altogether scrotal. It was first described by Béraud in 1856, who showed by dissection that the *tunica vaginalis propria* sometimes has very small diverticula. If a hydrocele form, one of these diverticula may become larger and protrude through some accidental rupture or inherently weak part of the *tunica vaginalis communis*. This protrusion might subsequently become so distended as to form the chief part of the swelling.

The *diagnosis* of this condition during life must be very uncertain. The form might be unusual, and the coverings would be very thin, so that translucency would be very marked. If the hydrocele be not tense, it is said that pressure will convey to the hand of the observer a sensation of fluid passing from the diverticulum into the parent sac. It is practically unimportant, for the *treatment* is similar to that of ordinary hydrocele.

B. HYDROCELE OF THE CORD.—Hydrocele occurs in the spermatic cord in two forms—*diffused* and *encysted*.

The *diffused*, which is very rare, is simply an oedema of the areolar tissue of the cord. When inconvenient, owing to its size, antiseptic incision and drainage should be undertaken.

Encysted hydrocele of the cord arises from a collection of fluid in the unobliterated funicular process of peritoneum, which is carried down in the natural transition of the testicle. It produces a small swelling in the cord, of an oval form, above and distinct from the testicle, more or less transparent, and quite movable. The swelling, when small, is of no importance; and it seldom requires treatment. When large it may be treated as though it were an ordinary hydrocele. See TESTES, Diseases of.

C. Hydrocele of a Hernial Sac is sometimes classed with hydrocele of the cord.

Where no definite history of a rupture is to be obtained, it may be difficult to distinguish this form from an encysted hydrocele of the cord, especially if the hernial sac is closed at its neck by adhesions or by a piece of omentum. An exploratory incision will probably clear up the diagnosis, when should it prove to be a hernial sac it should be ligatured at its neck and excised as in a radical operation for hernia.

JEREMIAH MCCARTHY.
F. SWINFORD EDWARDS.

HYDROCEPHALUS, Acute (ὕδωρ, water; and κεφαλή, the head).—A synonym for tubercular meningitis. See MENINGES, CEREBRAL, Diseases of.

HYDROCEPHALUS, Chronic. — SYNON. : Water on the Brain; *Hydrops Capitis*; Fr. *Hydrocéphale*; *Hydropisie du Cerveau*; Ger. *Der Wasserskopf*; *Hirnwassersucht*.

DEFINITION.—A gradual accumulation of serous fluid within the lateral and third ventricles of the brain, causing them to become more or less distended, and the head enlarged; occurring principally in infants or very young children; and leading to restlessness, irritability, or convulsions, followed by dulness, drowsiness, motor weakness, or actual paralysis, together with failure of mind and of the special senses.

The essential condition in this malady is the intra-ventricular effusion. The cases in which the fluid has been found outside the brain and within the arachnoid sac are, in all probability, merely examples of the disease in which, intra-ventricular effusion having previously been well marked, the distended corpus callosum, or, it may be, the floor of the third ventricle, has given way, and allowed the fluid to pass beneath the arachnoid. The so-called extra-ventricular form of the disease is therefore, in the majority of cases, merely a secondary and altogether accidental condition.

As a sequel of a large arachnoid hæmorrhage, serous fluid may also be found within the arachnoid cavity; this, however, is a condition which has no real title to be mentioned under the head of chronic hydrocephalus, as some writers have done. And the same remark applies to those accumulations of serous fluid which take place beneath the arachnoid, as a sequel of wasting or atrophy of the cerebral hemispheres, one or both. The collection of fluid in such cases is to be regarded as a simple sequel of the atrophy, and is of itself unproductive of morbid symptoms.

ÆTIOLOGY.—Two principal groups of causes are described. In certain cases, formerly known as 'essential,' the affection is believed to be due to inflammation of the lining membrane of the ventricles. In other patients, however, this affection is distinctly secondary or *symptomatic*, and then may be caused by one or other of two principal sets of conditions. Thus (1) it is often occasioned, as writers of the last century pointed out, by the pressure of scrofulous or other tumours upon the 'straight sinus,' producing mechanical congestion of the great veins of Galen as well as of their radicles on the walls of the lateral ventricles, and, as a consequence, an increasing dropsical condition of the ventricles themselves. Or else it may result from another mechanical cause, namely, closure of the foramen of Majendie and other minute apertures in the membranes closing in the fourth ventricle as a sequel of some form of meningitis. (2) Much more rarely it is said to be produced as a sequel of an attack of acute hydrocephalus. This latter mode of origin is admitted by some authors, and denied by others. It is at least a possible mode of origin, although one which it is difficult to establish with certainty. By far the largest percentage of cases probably belong to the first set of the 'symptomatic' category.

The disease is sometimes congenital, and may be so far developed during uterine life as to cause

great difficulties in parturition—frequently necessitating the sacrifice of the life of the child. At other times the enlargement of the head begins to show itself soon after birth, or at some period before the end of the first or second year. Or it may reveal itself later still in childhood; much more rarely during adolescence; and more rarely still in adult life.

Congenital 'microcephaly' must not be confounded with hydrocephalus. It is true that in certain small-headed infants, having the cranium malformed and the sutures ossified, an excess of fluid may be found within the head; but the fluid in these cases is situated outside the atrophied brain, and not within the ventricles. The two conditions are, in fact, totally opposite in nature.

ANATOMICAL CHARACTERS.—Three different states, in regard to size of head, have been described as existing in this affection:—(1) where the head is smaller than natural; (2) where the head is of natural size; and (3) where the head is more or less considerably enlarged.

Those of the first category ought not to be included at all. They are the cases of 'microcephalism' above referred to. Those of the second category could never be diagnosed with any degree of positiveness during life; and it may, indeed, be questioned whether such cases exist to any large extent, except as more or less transitory stages of instances of the disease pertaining to the third of the above categories.

Even the cases in which the head is distinctly enlarged differ among themselves, since in some of them (a) both sutures and fontanelles are widely open; while in others (b) the sutures, and perhaps the fontanelles, are completely closed. It seems probable that the latter may represent conditions into which some of the former pass, when the disease lapses into a chronic and stationary condition.

Owing to the separation of the cranial bones in young infants, this disease, when it occurs in them, soon becomes associated with an actual enlargement of the head, which increases rapidly. In consequence of the distending pressure from within, caused by the increasing size and fulness of the ventricles, the bones entering into the formation of the vault of the cranium become separated from one another, though the bones of the face remain unaltered. The frontal, parietal, the superior part of the occipital, and a small part of the squamous portion of the temporal bones become expanded and thinner than natural, at the same time that they are separated from one another—especially in the regions of the anterior and posterior fontanelles, and of the sagittal suture.

The cranial bones are often very thin, but occasionally they may be unusually thick throughout—even in young children.

The circumference of the head, even of a young child, may in hydrocephalus easily reach 24 to 30 inches, or more. The size attained by the head in certain cases has been comparatively enormous; thus, in an altogether exceptional case, recorded by Cruikshank, it is said to have measured, in a child sixteen months old, no less than 52 inches in circumference, and the amount of fluid contained within the cranium was found to weigh as much as twenty-seven pounds.

The fluid is generally slightly albuminous; possesses some saline constituents; and has a specific

gravity ranging from 1006 to 1014. Its composition agrees pretty closely with that of dropsical fluids generally.

In the great majority of cases, as already stated, the fluid is contained within the more or less distended lateral and third ventricles of the brain. The upper and lateral parts of the cerebral hemispheres, as well as the corpus callosum, become thinned and distended, so as to resemble a mere bag, the walls of which are represented externally by pale unfolded and much-flattened convolitional matter, and internally—next the fluid itself—by the lining membrane of the ventricles. This latter has become much thicker and tougher than natural; it may also be more or less granular on the surface; and often shows an increased number of distended vessels. These appearances are, however, not to be taken as an indication of the inflammatory origin of the malady, as some observers seem to suppose. They may be found, as the writer has seen, well masked, in cases where the effusion and distension have been the result of a mere mechanical congestion, produced by pressure upon the commencement of the straight sinus, owing to a tumour in the middle lobe of the cerebellum. On the other hand the writer has examined a case, in which the most careful search revealed nothing that could have produced mechanical congestion, and in which there was, moreover, no sign of anything like an inflammatory condition of the walls of the greatly distended lateral ventricles.

The shape of the ventricles and of the compressed ganglia about the base is, of course, greatly altered. The foramen of Munro may be half an inch or more in diameter. The optic and olfactory tracts and lobes are also often much altered by pressure.

The brain-substance may be even tougher than natural, because the long-continued mechanical congestion, which exists in so many cases, favours the overgrowth of the neuroglia. The brain of a hydrocephalic child, after the fluid has been evacuated, commonly weighs more than the brain of a healthy child of the same age.

In those cases in which during life the fluid has escaped from the ventricles through a rupture in the corpus callosum, the brain has been found more or less flattened and collapsed in the lower part of the enlarged cranium, while the escaped fluid occupies the arachnoid cavity above it.

SYMPTOMS.—Chronic hydrocephalus begins to manifest itself in various ways, and also, as above stated, at various ages. The great bulk of the cases are either congenital, or commence before the fifth month. But, in certain rare instances, the head may begin to enlarge long after the union of the sutures, in early adult life, or even beyond middle age.

As to modes of commencement, at least four, pretty distinct from one another, may be encountered. (1) The disease may be ushered in by a period of fretfulness and irritability, with or without the occurrence of convulsions and strabismus, before any enlargement of the head is detected. Or (2) slow enlargement of the head may be noticed as the first event. In some cases, this enlargement not only sets in, but may continue for months, till notable increase in size has taken place, and yet the child may exhibit no morbid symptom whatever. The writer has seen a well-marked instance of this in a child whose head had been enlarging for eighteen months (the process beginning when

it was a year old), and in whom, though the head was twenty-four inches in circumference, no other morbid signs or symptoms presented themselves.

(3) Chronic hydrocephalus may supervene in a child after a fall, through the intermediation of cerebellar disease. The writer had under his care a little girl four years old, who, after falling from a table and striking the occiput severely, suffered for from twelve to eighteen months from symptoms indicative of cerebellar disease, after which the head began to enlarge, and hydrocephalus became the apparently dominant condition. Complete blindness ensued, then convulsions set in, and in the midst of one of these the patient died. A tumour of the middle lobe of the cerebellum was found, *plus* all the signs of a well-marked hydrocephalus. (4) The disease may occur as a sequel of an attack resembling acute hydrocephalus (tubercular meningitis); that is to say, a child appears to suffer for a time from what is regarded as tubercular meningitis; the symptoms then undergo some mitigation; they become more or less chronic; and ultimately the head begins to enlarge, as in chronic hydrocephalus. There is some doubt about the real nature of these cases. The initial symptoms may not in reality have been those of tubercular meningitis. The chronic disease and its symptoms may occasionally be initiated in an acute manner. See MENINGITIS, POSTERIOR BASIC.

It may be easily imagined that the subsequent course of the symptoms in persons suffering from chronic hydrocephalus, beginning in these various ways, may also be subject to great variations.

As the head enlarges, or as the pressure within increases, sensations of weight or pain may be experienced. The child may show increased fretfulness and irritability; or its manner may become more dull and heavy than natural. At other times there is no noticeable change in these respects.

In the 'symptomatic' forms associated with tumours, there is apt to be vomiting of a very obstinate and paroxysmal character, together with continuous pain, marked by exacerbations. Convulsions, either unilateral or general, may also occur, as well as paralysis of one or other of the ocular muscles. In such cases, too, in comparatively early stages, ophthalmoscopic examination will frequently reveal optic neuritis, which has a tendency to go on to white atrophy, with the production of more or less complete blindness.

In later stages of the disease mental action becomes increasingly impaired; there is loss of memory, dulness, and a great tendency to sleep during the day. There may be marked weakness or actual paralysis of limbs. Children affected to this extent often keep to the recumbent position, having at last no power of sitting up, or even of raising their head from the pillow. Where the enlargement becomes extreme the weight of the head is so great that it cannot be maintained in the upright position. It has to be supported by the hand or some artificial prop; or else the child does not attempt to rise from the recumbent position. A sense of fluctuation is often recognisable. The forehead becomes prominent and overhanging, while the eyeballs are depressed; and as the face remains unaltered or even becomes emaciated, it seems altogether unnaturally small, and thus contributes to produce a most characteristic appearance ('*facies hydrocephalica*'), which is often intensified by the old-looking, and more or less blank, expressionless

aspect of the face. The appetite sometimes remains good; at other times it becomes much impaired, and a gradual emaciation ensues. Blindness, more rarely deafness, loss of smell, and impairment of other senses tend gradually to reveal themselves after a time.

COMPLICATIONS.—In all cases where the hydrocephalus is itself symptomatic of some primary intracranial disease, interfering with the proper return of blood from the ventricles and central portions of the brain, the symptoms resulting from this latter state of things are necessarily complicated with others immediately produced by the original morbid condition. Hence the very great variations encountered in the grouping of symptoms in different cases.

DIAGNOSIS.—Where the head becomes distinctly enlarged, with widely separated sutures and open fontanelles, there can be scarcely any room for doubt about the diagnosis. But before the head is distinctly enlarged, the diagnosis of chronic hydrocephalus with any degree of certainty is impossible. In many cases also where the head is only slightly enlarged, and the sutures are not opened, it may be very difficult, for a time, to pronounce an opinion as to whether or not an infant or young child is hydrocephalic. Natural variations in the size of the head are considerable; and it may also be enlarged from rickets, or from that very rare condition known as 'hypertrophy of the brain.' Even great thickenings of the bones of the head have occasionally given rise to uncertainties in regard to diagnosis. But in all these cases, in order to enable the practitioner to arrive at a trustworthy opinion, the particular form of the head has to be considered, together with the sum total of the various symptoms which may have preceded or accompanied its increase.

Whether we have to do with an instance of 'essential' or of 'symptomatic' hydrocephalus in any particular case often cannot be settled; but in others it can be decided by the existence of symptoms distinctly pointing to the presence of an intracranial new-growth.

COURSE AND TERMINATIONS.—Hydrocephalus often proves fatal in the course of a few months; or it may be less rapid, entailing death only after a year or two. Its progress is variable, however. Remissions and stationary conditions are apt to occur, with occasionally distinct exacerbations of all the symptoms.

Occasionally one of these stationary conditions becomes prolonged, and the individual may live for years. Some hydrocephalic subjects have subsequently lived on to the age of twenty, thirty, or even forty years. In a few exceptional cases a cure seems to have been effected, either naturally or under the influence of remedial agencies.

Death may take place in convulsions; from slow exhaustion with emaciation; or from intercurrent pneumonia or some other acute disease.

TREATMENT.—Very little, unfortunately, can be done, in the majority of cases, to produce decided or lasting improvement. This is especially so in those instances—only too numerous—in which the hydrocephalus is due to some scrofulous or other tumour interfering with the return of blood from the ventricles.

Blistering the scalp, with mercurial inunctions, formerly much lauded, may do a great deal more harm than good; and the same may be said in

reference to pressure of the enlarged head by strapping or bandages. This latter is a barbarously coarse method of treatment, which has happily fallen into disuse. Blistering may do good in some cases, but it should be cautiously employed.

The general health of the child must be maintained as much as possible, by the aid, if necessary, of tonics and cod-liver oil. Purgation and diuretics may also be had recourse to. Iodide of potassium may be given internally in gradually increasing doses, as even young children bear this remedy well. Bromide of potassium will also help, perhaps, to mitigate vomiting and convulsions, when these are urgent symptoms.

It may be worth while in suitable cases to try the effect of greatly diminishing the amount of fluids taken, so as to reduce the fulness of the vascular system. The writer has had reason to believe that this method is well worthy of being tried, where other means have failed, and where there is any chance of being able to carry it out.

Puncture of the head and withdrawal of small quantities of the fluid with various precautions has been occasionally practised, but with no satisfactory results. Attempts have recently been made to secure drainage of the lateral ventricles in cases of hydrocephalus by establishing a permanent channel between these cavities and the subarachnoid space. The pressure of fluid within the latter is found to be constantly equal to that within the cerebral veins, this equality being due to the even balance of secretion and absorption. If, therefore, such a channel could be kept open, a constant equable drainage of the ventricle would theoretically result. For this purpose bundles of strands of catgut and metal tubes have been introduced and left *in situ*, one end communicating with the ventricle, the other lying in the subarachnoid space, so that fluid could pass freely along them. The results obtained, however, have so far been disappointing. Surprising diminution has indeed occurred at times in the size of the head, but no permanent cure has been effected, and death has occurred in spite of some temporary amelioration of symptoms. This is probably due to two causes: on the one hand the softness of the cerebral substance tends sooner or later to block any channel made, and thus to prevent drainage; on the other, these cases are generally treated at so late a period that fatal mischief to the brain has probably resulted before relief has been afforded.

HYDROMETRA (ὕδωρ, water; and μήτρα, the womb).—Dropsy of the womb. See UTERUS, Diseases of.

HYDRONEPHROSIS (ὕδωρ, water; and νεφρός, the kidney).

DEFINITION.—A disease (usually chronic) of the kidney, generally produced by obstruction of the ureter. The obstruction leads to dilatation of the renal pelvis, and frequently of the ureter itself, the condition of the latter depending on the site of the obstruction. The dilatation and distension not only involves the pelvis and the calices of the kidney, but also the renal substance which is stretched out in the form of a layer of varying thickness. In the extreme forms of the disease one kidney only is affected, in the milder forms both may be involved. In some varieties of hydronephrosis the distension of the organ is intermittent,

and in rare instances the intermittence is, in women, associated with the menstrual period. The distension of the kidney frequently causes the appearance of a tumour of considerable size, and in the intermittent varieties of the disease the partial or complete disappearance of this tumour may occur from time to time. The fluid distending the tumour is not normal urine, as the percentage of solids and of urea in it is very low; albumen in small quantity is often present, and in some cases blood.

ETIOLOGY.—Hydronephrosis is most frequently dependent on obstruction of the ureter produced by the impaction of calculi or as a result of pressure caused by uterine, ovarian, and other pelvic growths, but especially by carcinoma of the uterus. Obstruction by calculi may be due to their impaction either at the junction of the pelvis of the kidney with the ureter or at the opening of the ureter into the bladder. Impaction of a calculus does not always lead to hydronephrosis; in some cases it may cause complete suppression of urine. Chronic peritonitis, pelvic peritonitis, and cellulitis may also produce obstruction of the ureter and hydronephrosis. Congenital anomalies, such as preternatural narrowness of the ureter or the implantation of the ureter at an acute angle into the pelvis of the kidney, not infrequently cause hydronephrosis. Movable kidney in its more extreme forms may also give rise to this condition, especially where great mobility of the organ is associated with congenital narrowing of the ureter. In rare instances anomalies of the renal artery may cause hydronephrosis on account of the pressure exerted by the anomalous artery on the ureter. Intermittent hydronephrosis is more especially associated with calculus, movable kidney, and pelvic peritonitis. Hydronephrosis recurring with the menstrual period is sometimes seen as a sequel of pelvic peritonitis or of calculous obstruction, and is apparently due to the catamenial turgescence of the pelvic organs aggravating, to a sufficient extent to cause hydronephrosis, some slight obstruction due to one or other of these pre-existent causes. In rare instances a slight degree of hydronephrosis may be dependent on such a remote cause as the obstruction due to phimosis.

Hydronephrosis is sometimes congenital and dependent on atresia of the ureters produced during fetal life; such congenital hydronephrosis may produce so great an enlargement of the kidney as to cause difficulty in labour.

MORBID ANATOMY.—In the slighter forms there is dilatation of the pelvis and calices of the kidney with some flattening of the papillae. In the more extreme forms the kidney presents the appearance of a bag, the interior of which is imperfectly divided by a number of septa which owe their origin to the fibrous walls of the calices. The renal tissue is stretched out as a layer of varying thickness, at times no more than an eighth of an inch. In some cases the pelvis of the kidney is distended to the size of an orange; in others the distension of the pelvis and the ureter is more uniform. In the slighter forms the principal alteration in the histology of the kidney is that the cells lining the tubules become hyaline and glass-like, losing their characteristic granular structure. In the more severe forms considerable desquamation of the epithelium occurs, and the interstitial tissue between the tubules becomes increased in amount. In old-standing cases the wall of the hydronephrotic sac is very largely fibrous.

SYMPTOMS.—Where the disease is partial and double, e.g. where it occurs as a complication of carcinoma uteri, it may be entirely overlooked unless special attention is directed to the probability of its occurrence. Frequently its presence is only suspected owing to the secretion of a dilute urine, and then palpation in the loins may reveal the presence of enlarged kidneys. In other forms, where the hydronephrosis is more complete but unilateral, the patient may come under observation owing to the presence of a swelling in the loin, which presents usually the typical characters of a renal tumour. In many such cases no other symptoms are presented even where the tumour is of large size. In others pain is a prominent symptom, and this is more especially the case in the intermittent varieties associated with movable kidney, calculus, &c. The pain is usually lumbar and abdominal, and does not radiate into the groin or down the thigh; it is often accompanied by nausea, vomiting, faintness, and in some cases, even where suppuration of the contents of the sac does not occur, by considerable fever. The sudden disappearance of the pain and subsidence of the tumour, accompanied by an increased flow of urine, are most characteristic symptoms of the intermittent form of the disease. The renal tumour produced by hydronephrosis has rounded outlines, and is sometimes said to be lobulated. Fluctuation can often be detected by palpation in the abdomen and the loin.

Hydronephrosis when double causes death from uræmia, and this occurs even when the obstruction is partial so as to produce only moderate distension of the kidneys. Unilateral hydronephrosis may cause serious symptoms from pressure on other organs, as, for instance, the bowel.

DIAGNOSIS.—The differential diagnosis of unilateral hydronephrosis has to be made from splenic, ovarian, and hepatic tumours, from pancreatic cysts, and from hydatids of the liver and of the peritoneum. Where the hydronephrosis is of large size it may be confounded with localised ascites. The distinction between hydronephrosis and pyonephrosis is sometimes difficult, as fever is not an invariable accompaniment of the latter, and may be present in the former.

PROGNOSIS.—Prognosis depends essentially on the cause of the hydronephrosis. Where the condition is a bilateral one, as in uterine carcinoma, prognosis is most serious. Where the disease is unilateral, the prognosis depends on the condition of the opposite kidney; and provided the hydronephrosis does not cause severe pain, and the opposite kidney is sound, the disease may cause comparatively little inconvenience. In some cases, however, severe pain is present owing to great or rapid distension of the kidney.

TREATMENT.—In cases of unilateral hydronephrosis surgical treatment is generally required. Drainage of the kidney is usually resorted to, but in many cases nephrectomy is ultimately required, as the obstruction to the ureter may be such that it cannot be relieved, and thus a sinus discharging urine is left as a result of a draining operation. Where the hydronephrosis results from calculous obstruction surgical interference may be successful in removing the obstruction. In bilateral hydronephrosis little can be done, and the condition is a most serious complication of the primary disease causing it.

JOHN ROSE BRADFORD.

HYDROPATHY (ὕδωρ, water; and πάθος, a disease).—A synonym for hydrotherapeutics. *See* HYDROTHERAPEUTICS.

HYDROPERICARDIUM (ὕδωρ, water; περί, about; and καρδία, the heart).—An accumulation of dropsical fluid in the pericardium. *See* PERICARDIUM, Diseases of.

HYDROPHOBIA (ὕδωρ, water; and φόβος, fear). **SYNON.**: Rabies; Fr. *Lyssa*; la Rage; Ger. *Hundswuth*; *Wasserscheu*.

DESCRIPTION.—Hydrophobia is an acute infective malady of the central nervous system. The specific virus, the exact nature of which is undetermined, is found abundantly in the central nervous system and more especially in the medulla.

The disease is one common to man and many of the lower animals, and it is customary to restrict the term hydrophobia to the disease in man, and rabies to that in animals. The term 'hydrophobia' is, however, not strictly accurate, as there is not necessarily any fear of water during the height of the disease, but only great difficulty in swallowing liquids; the attempts to swallow bring about attacks of convulsions, and not uncommonly the mere sight of the water or other substance provokes similar attacks.

ÆTIOLOGY.—The disease is never spontaneous, but is usually communicated through the bite of a rabid animal and the consequent inoculation with the virus that is present in the saliva. In the great majority of cases the disease is communicated to man by the bites of rabid dogs, occasionally of cats, and in rare instances of foxes and wolves. The prevalence of rabies in Russia is due largely to the frequency of wolf-bites. Hydrophobia is more apt to follow bites on exposed parts of the body such as the face and hands. Instances are on record where the disease has occurred as the result of the hand being licked by a rabid animal, and then the infection must be dependent upon the presence of some abrasion. Deep lacerated wounds are more liable to be followed by the disease than superficial bites involving only the skin and subcutaneous tissue. The bites from rabid cats are more dangerous than those from dogs, owing to the tendency of the cat to 'fly' at and bite exposed surfaces such as the face and hands. Wolf-bites are dangerous owing to their severe and lacerated nature. It has been asserted that the disease may arise from the bite of a healthy dog, but this is not the case; the mistake has arisen from the fact that a dog may communicate the disease while suffering from the initial manifestations of the illness, and before the characteristic symptoms have been developed (*see* **RABIES**). A considerable proportion of persons who are bitten by rabid dogs do not develop hydrophobia, and it has been estimated that only from 16 to 25 per cent. of persons so bitten develop the disease. Other authorities state that when no preventive measures are adopted half or even two-thirds of those bitten escape. There is great difficulty in determining this question with accuracy owing to the difficulty of obtaining evidence that the dog or other animal reputed to be rabid was really so. The virus of rabies is not only present in the fresh saliva, but the latter when dried retains its virulence for some days (*see* **RABIES**). Hydrophobia has in rare instances been acquired through a wound received during the *post-mortem* dissection of a rabid animal.

The *incubation-period* of hydrophobia in man is usually six weeks; it has been asserted that it may be as short as three weeks, and in exceptional instances incubation-periods of twelve or even of eighteen months have been described. It is more than probable that in the latter instances some fallacy was introduced: either that the disease developed was not hydrophobia, or else that a fresh inoculation has occurred without the patient's cognisance. It is quite possible for hydrophobia to be communicated to the human subject by the lick of a dog suffering from the disease as mentioned above, or even, as in a case mentioned by Gowers, by the unloosening with the teeth of a knot on a rope with which a rabid dog had been tied. Such modes of infection as this make it probable that in the cases with long incubation-period there has been really a fresh infection.

MORBID ANATOMY.—The most characteristic naked-eye features in *post-mortem* examination are congestion in the fauces, larynx, trachea, and stomach, and fluidity of the blood. The salivary glands sometimes show obvious signs of congestion, and in some cases congestion of the central nervous system, and more especially of the medulla, is visible to the naked eye. A number of observers, more especially Clifford Allbutt and Gowers, have described an accumulation of leucocytes around the vessels and the infiltration of the adjacent tissue of the bulb with similar cells. This change has a special distribution, as it is most marked in the region of the medulla, more especially in the lower part of the fourth ventricle in the vicinity of the respiratory centre. Gowers described the change as most intense in the hypoglossal, glosso-pharyngeal, and vagal nuclei. Similar conditions are present in the cerebral convolutions and also in the spinal cord. There is little or no affection of the upper part of the medulla, cerebellum, or basal ganglia. In addition to the above changes minute extravasations of blood may occur, and the ganglion-cells of the parts affected have been described as undergoing granular degeneration. Babes also describes hyaline degeneration of the vessels of the spinal cord and brain; he states that in some cases actual obliteration of the vessels may thus be produced. The salivary glands may also show evidence of inflammation on microscopical examination.

SYMPTOMS.—During the incubation-period there are usually no symptoms, and the wound heals without producing any signs of general disturbance. Towards the end of the period of incubation, the site of the wound may become irritable, and tingling and itching often occur. Doubtless in some instances this is dependent on the fact that the patient's attention is directed to the bite, but in other cases these sensory symptoms may be very marked and too pronounced to be thus explained. During the latter part of the incubation-period the patient's mental condition may also become altered, and depression, restlessness, and nervousness become marked. These latter symptoms, however, are perhaps more accurately described as the initial symptoms of the actual malady. In most instances the outbreak of the disease is not accompanied by any local phenomena in the wound; in others the sensory symptoms described above become more marked so that actual pain is experienced, and it has been stated that the wound may break open. The invasion in man is usually accompanied by considerable mental depression along with some

tightness or other unpleasant sensation about the throat, and sleep becomes disturbed. There is often marked pallor, slight and intermittent delirium may be present; and the patient complains greatly of thirst. Very soon, however, there is distinct difficulty in swallowing, especially of liquids, and the attempt to swallow causes spasmodic contraction of the muscles of the throat so that the fluid may be expelled from the mouth. Very soon the spasm is not confined to the muscles of deglutition but involves also those of respiration, occasioning what has been called a 'catch in the breath.' The violence of the respiratory spasm rapidly increases so that in a very few hours what was merely a catch in the breath becomes a violent inspiratory effort. Later still the spasm is no longer limited to the muscles of respiration but becomes more widely spread, so that general convulsive attacks recur at every attempt to swallow.

During the initial stage of the disease, while the spasms are still limited, the mental anxiety and dread of the patient increase, although consciousness is retained, and the patient may be quite rational and able to talk, the interference with respiration being only slight, and causing a mere temporary interruption of his speech. The restlessness and agitation, however, rapidly increase and produce a condition of extreme dread and fearfulness, which is one of the most characteristic features of hydrophobia. The extreme dread may only exist intermittently, but more usually it continues and undergoes an increase during the paroxysmal seizures. It is stated that during the paroxysm the frenzy of the patient is such that he may attempt to bite those round about him, but in the few cases of hydrophobia that the writer has seen this has never occurred. Consciousness is usually retained in the intervals between the paroxysms. The convulsive attacks in the fully established disease are not only produced by attempts to swallow, but may be excited by the mere sight of water or food, or even by any other slight visual or auditory stimulus, such as the light falling on the bed or a person entering the sick room. Vomiting may occur, and is sometimes an early symptom. There is usually some pyrexia at the onset of the disease, the temperature being raised two or three degrees. In exceptional instances it may rise as high as 105° F. Albumen and sugar may be present in the urine, and priapism is occasionally a marked symptom. The saliva frequently accumulates about the mouth, and the difficulty of getting rid of the accumulated mucus, owing to the partial palsy of the respiratory and other muscles, leads to a peculiar cough, which is the ground for the statement that the patient may 'bark like a dog.' Similarly the frothing at the mouth is dependent on the saliva and stringy mucus adhering to the lips. The duration of the disease in man after the onset of symptoms is usually four days or less. Cases lasting six, eight, and even ten days have been described. Death commonly occurs from exhaustion or from asphyxia, due to palsy of the respiratory mechanism. Some cases are said to die from cardiac failure, and exceptionally general paralysis like that seen in rabies occurs.

VARIETIES.—Although the above description applies to the great majority of cases, in some the mental symptoms, such as restlessness and furious excitement, may occur early in the course of the disease, before the characteristic features of the malady can be detected, and may thus produce a

clinical picture resembling acute mania. In others, but more rarely, a condition similar to paralytic rabies (*see RABIES*) is produced, that is to say, an ascending paralysis involving first the extremities and finally the muscles of respiration. It is probable that paralytic rabies has occurred in man, and most frequently as the result of the bite of a rabid cat. In ordinary hydrophobia death occurs prior to the onset of marked paralysis, but in these paralytic cases the condition is not preceded by any of the ordinary convulsive symptoms.

PATHOLOGY.—The virus of rabies is probably dependent upon the activity of some micro-organism, although the existence of such an organism has not been clearly established. The disease exhibits some resemblances to tetanus, in which it has been shown that the principal phenomena of the malady are produced by the toxic substances elaborated by the specific bacillus. The most remarkable fact about the virus of rabies is the power that it possesses of increasing in the nervous system. In the earlier stages of the malady the virus is present most abundantly in the medulla, but before death it is found throughout the nervous system. It is, however, not limited to this, but is also found in the saliva (especially, it is said, in the parotid saliva) and also in the secretions of the lacrymal, mammary, and pancreatic glands. Most observers are agreed that it is not present in the blood or in the tissues of the body generally, nor in any of the excretions or secretions except those mentioned. The virus is also found in the peripheral nerves, and may be present in the supra-renal bodies. There is some evidence tending to show that the virus inoculated by a bite reaches the central nervous system through the nerves, and it is perhaps for this reason that lacerated wounds involving nerves are more liable to be followed by the disease. It is possible that the virus may be conveyed from the peripheral nerves to the central nervous system through the lymphatics. The action of the virus is of such a character as first of all to increase the functional activity of certain of the bulbar centres, and more especially to exaggerate their reflex excitability, in a manner somewhat analogous to the action of strychnine. This is especially seen in the fact that the spasm produced first of all by attempts at swallowing may, instead of being localised to the muscles of deglutition, spread to other groups, and so produce a general convulsive seizure. Further, the reflex excitability is so increased that these convulsions may be brought about by other and slighter causes, such as visual and auditory stimuli. In this respect the action of the virus of rabies possesses a certain resemblance to that of strychnine, though in the case of the latter substance the main effects are exerted on the reflex functions of the cord, whereas in the case of the former the primary effect is exerted on the bulbar centres. The excitatory effect produced by the virus of rabies is, however, an initial one, and is followed by a condition of depressed activity of these centres and of those in the spinal cord, resulting in palsy. The action of the virus of rabies, however, is not limited to the bulbar and spinal centres, since it produces excitatory effects also on the cortical centres, in this way causing mental excitement, delirium, and even mania.

DIAGNOSIS.—The clinical diagnosis of hydrophobia does not usually present very great difficulties, owing to the peculiar character of the

respiratory spasm. Further the mental phenomena, and especially the great dread that is so characteristic of the malady, afford useful aids, and in a number of cases the history of a bite can be obtained. Hystero-epilepsy, mania, and tetanus are the diseases which are most liable to be confounded with the ordinary form of hydrophobia in man. From tetanus it can usually be distinguished not only by the characteristic respiratory spasm, but also by its long incubation-period, and by the absence of trismus and of that persistent rigidity which is seen in tetanus. A mistake is only liable to arise if too much stress is laid on convulsive seizures, since these are often very well marked in cases of hydrophobia. In some cases considerable difficulty may be experienced in distinguishing between hydrophobia and acute mania, and here again stress must be laid on the presence of the respiratory spasm and the history of a bite. In some cases, perhaps, clinical differentiation between the two diseases is impossible, and in rare instances it has been only by experimental inoculation after death that cases of supposed mania have been proved to be cases of hydrophobia. The difficulty perhaps that presents itself most often is to distinguish between hydrophobia and functional disturbance of the nature of hystero-epilepsy, to which the term 'lyssophobia' has been applied. This is a condition which is apt to arise in persons who have been bitten by a dog and who have a great dread of hydrophobia. In lyssophobia difficulty of swallowing may be present, but it is of the nature of globus hystericus, and is accompanied by hysterical convulsions; true respiratory spasm, such as is seen in hydrophobia, is not present. It is probable that hydrophobia is more often mistaken for mere functional disturbance than *vice versa*. In the spurious form the symptoms soon subside with the application of ordinary remedies directed to soothing the patient's mental excitement. It is stated that difficulties in differentiating between hydrophobia and certain organic brain-diseases accompanied by convulsions and delirium may sometimes arise.

PROGNOSIS.—Hydrophobia is looked upon as an almost invariably fatal disease, although it is stated that recovery has, in very exceptional instances, occurred in man. There must, however, always remain a certain amount of doubt as to the exact nature of these cases. When the symptoms of the disease are once fully established, the patient usually dies within four days.

TREATMENT.—The most essential point is unquestionably the prevention of hydrophobia by adequate measures directed to prevent the occurrence of rabies. See **RABIES**.

When the patient has been bitten by an animal suspected of being rabid, the animal should be isolated with efficient precautions to prevent danger to others, since observation of the phenomena exhibited by the animal will in a very few days determine with certainty the question whether it is or is not rabid. If the suspected animal be immediately killed, as is often the custom, this may involve the delay of three weeks or more in determining with certainty the existence or non-existence of rabies. The circulation should be temporarily arrested in the part bitten by compression above the seat of the bite, and the wound should be thoroughly washed as soon as possible, and efficiently cauterised with strong nitric acid

or with a strong antiseptic such as carbolic acid. Nitrate of silver may be used for the purpose, but is not such an efficient caustic as nitric acid. The actual cautery may also be used, and it is probable that excision of the part bitten is beneficial. Cauterisation without arrest of the circulation is not very efficient. The wound may be sucked if there are no wounds or abrasions on the lips or in the mouth of the person performing this act; the mouth should at once be thoroughly washed out with some efficient antiseptic. It is usually stated that the disease does not ensue if efficient cauterisation with temporary arrest of the circulation be immediately carried out after the bite, and if the wound is a simple one. If the animal that has inflicted the bite is definitely known to be suffering from rabies, the patient should undergo the prophylactic treatment of Pasteur with as little delay as possible. It is very unwise for the treatment to be delayed until experimental evidence is obtained of the existence of rabies in the animal, as this may involve a delay of three weeks, and the Pasteur treatment requires a fortnight for its performance.

In the *Pasteur treatment* an emulsion prepared from the desiccated spinal cord of a rabid rabbit is injected subcutaneously, and the treatment is based on the fact that desiccation causes a progressive diminution in the activity of the virus present in the central nervous system. On the first day of the treatment an emulsion of the spinal cord that has been desiccated for fourteen days is employed; on the second day a similar emulsion prepared from a cord desiccated for twelve days is given, and so on, until on the fifteenth day of the treatment an emulsion of a spinal cord that has only been desiccated for three days is injected. A large body of facts have been published in the 'Annales de l'Institut Pasteur,' showing that by this mode of treatment the number of cases of hydrophobia occurring in man from the bites of rabid animals has been diminished to less than one per cent. The treatment to be efficacious should be begun within a week of the infliction of the bite.

Various attempts have been made to prepare an antitoxic serum by injecting the attenuated virus of rabies into animals, and there is a considerable amount of evidence that under these circumstances the blood of sheep and other animals develops an antitoxic substance, and that a protective serum may in this manner be prepared. Although this has been shown to possess valuable properties, it has not been used in the prophylactic treatment to the same extent as the Pasteur method.

When the disease has declared itself in the human subject little can be done except to relieve the more distressing symptoms. A large number of remedies have been vaunted as capable of curing the disease, the most notorious of these being the well-known vapour-bath treatment. This has been shown to be entirely useless in the genuine disease, the reported cures being in all probability cases of so-called lyssophobia. Chloroform, morphine, bromide of potassium, and chloral hydrate may all be used to diminish the violence of the convulsions and to allay the sufferings of the patient. Curare has also been employed in this disease, and it has apparently been successful in a small number of instances. This drug is tolerated in large quantities in this disease, and may be given in doses of from one sixteenth to one third of a grain, repeated every quarter or half hour, until the severity of the

paroxysms is lessened (Gowers). There is considerable risk of producing in this way such a degree of muscular palsy as to necessitate recourse to artificial respiration. The patient should be placed in a darkened room and absolute quiet maintained, since sudden noises, the presence of strangers, or light, may all produce convulsions. As much nourishment as possible should be given, and owing to the difficulty in swallowing it should be administered *per rectum*. Tracheotomy is probably useless. Those in contact with the patient should take care that in his struggles and furious excitement they are not bitten, and should disinfect the face or hands from any contamination by the saliva. A bite inflicted by a person suffering from hydrophobia should be treated in the same manner as one from a rabid animal. The danger, however, is small, as there is no record of the disease having been communicated from one human being to another.

JOHN ROSE BRADFORD.

HYDROPS (ὑδῶρ, water).—A collection of drop-sical fluid in any part of the body. See DROPSY.

HYDRORRHACHIS (ὑδῶρ, water; and ῥάχις, the spine).—A collection of fluid in the spinal canal. The term is commonly used as a synonym for spina bifida. See SPINA BIFIDA.

HYDROSALPINX (ὑδῶρ, water; and σάλπιγξ, a tube).—A local collection of serous fluid in a Fallopian tube. See FALLOPIAN TUBES.

HYDROTHERAPEUTICS (ὑδῶρ, water; and θεραπεύω, I treat).—SYNON.: Water-cure; Hydro-pathy; Fr. *Hydrothérapiutique*; Ger. *Wasser-heilkunde*.

This article contains (1) notes on the internal use of water, and on the more common hydrotherapeutic procedures; and (2) a consideration of the morbid conditions suitable for hydrotherapeutic treatment.

Internal Therapeutic Use of Water, and the more Common External Hydrotherapeutic Procedures.—The dietetic necessity of water is well known; life cannot exist without it; all our tissues contain an indispensable proportion of water; we constantly lose a large amount by respiration, and by all excretions; all the internal functions of tissue-change are dependent on a certain quantity of water. This want is supplied by the solid and fluid food which we take, water included; while temporary excess of supply leads to increased discharge by the excretions, and temporary deficiency to a diminution of the water of the excretions. An increased ingestion of water further leads, for a time at least, to an increased removal of the products of retrogressive tissue-change; the tissues and the blood itself are, so to speak, washed out by it; and, as the consequence of the increased removal of the used-up material, the body is enabled to take in a larger amount of new substance, and hence we observe not rarely increase of weight as the effect of plentiful water-drinking, if not carried to excess as regards quantity and time; the secretions of the urine, bile, saliva, and pancreatic juice appear to be increased by the abundant internal use of water, as well as the perspiration; though the latter to some degree requires the concomitant influence of high external temperature or bodily exercise.

Water has also an important share in all internal

courses of mineral waters. Used by itself, it can exercise some good influence in cases of gout and gravel, in hæmorrhoidal complaints, imperfect secretion of bile, and constipation from sluggish peristaltic action. As, however, excessive water-drinking, according to Priessnitz's original plan, is apt to cause dyspeptic troubles, water is now, in general, used internally only either for dietetic purposes, or to assist in other courses of treatment.

The *external use* of cold water admits of a very great variety of applications, and a corresponding variety of effects on the body. The two main effects of the different forms of cold baths are *abstraction of heat*, with its further influences on the functions of the body; and *stimulation of the cutaneous nerves*, and through these of the nerve-centres. The two effects are usually combined, but in some forms of bath the stimulation or the *exciting effect* preponderates; in others the abstraction of heat, with its *calming or depressing influence*. Hence the different forms of baths, or rather hydrotherapeutic procedures, may be divided into *stimulating and calming*, but it is to be borne in mind that there is no strict line of distinction. With this limitation we may regard as *stimulating*—the full cold bath of short duration, the stimulating action of which is increased by motion of the water, be it natural or artificially imparted; the rapid wash-down, either by means of a large sponge, or a wet sheet, with or without friction; the spouting of the back, and the pail-douche; the needle-bath or circular shower-bath; the different forms of the rain-bath, and the usual shower-bath; the great variety of other douches; and the running or flowing sitz-bath. The immediate effects of these stimulating forms, in a constitution endowed with a certain amount of reactive power, are exhilaration, increased activity of circulation and muscular force, and improved appetite and digestive power. By altering the duration of the bath and the temperature of the water, the effects may be considerably modified, and thus adapted to different conditions. In adult as well as young persons, most beneficial effects are often produced by the combination of warm baths with cold douches on the spine.

The more *calming* forms are—the wet sheet-envelope, entire or partial; the impermeable wet compresses; the full cold bath of long duration and without motion; the sitz-, the shallow, and foot-baths without motion; and the full bath of higher temperature. Depression through abstraction of heat exceeds the stimulation in these forms: diminution of nervous irritability, of sensation and mental activity, and of the frequency of the pulse and energy of circulation; a feeling of lassitude; and a tendency to sleep, are the principal effects. These forms can, however, be modified, and the effects vary in proportion. Thus the wet sheet-envelope allows ample variation by using warm or cold water, by using the sheet dripping or wrung out, by making it fit tightly round the neck, by moving it to and fro, by frequently changing it, &c. The calming and stimulating form may be further combined by using, first, the wet sheet-envelope, or the woollen blanket-envelope, for a sufficient period to produce perspiration; and then a more or less cold bath or shower-bath of short duration. The physician has, indeed, infinite varieties of application at his disposal, to be used according to necessity.

Powerful and most important hydrotherapeutic helps are the different vapour- and hot-air baths (Russian, Roman, Turkish), combined with douches and baths of various temperatures. These kinds of baths are, however, treated of in another article. See BATHS.

A plain nourishing diet, without or with only a limited amount of stimulants; outdoor exercise in proportion to the strength of the individual; and in some cases massage, in others active or passive gymnastics, are likewise to be regarded as valuable adjuncts in the hydrotherapeutic treatment of chronic diseases; for massage and muscular exercise mean not only increased action, oxidation, excretion, and development of muscle, but also increased general circulation and respiration, increased inhalation of oxygen, and increased production of heat, so necessary in the cold water-cure. There is also no reason whatever why suitable pharmaceutical remedies should not be combined with the water-cure treatment—a method which, as already mentioned, is frequently adopted in the best establishments.

Therapeutic Effects, and Morbid Conditions suitable for Hydrotherapeutic Treatment.—The principal results of well-adapted courses of cold-water treatment are: improved nutrition and action of the skin; increased tone of the nerve-centres; regulation of the circulation; amelioration of the sanguification and nutrition; and acceleration of the retrogressive tissue-changes. It is essential for such successful results that the organism be able to stand a certain amount of abstraction of heat; that it be capable of more or less energetic reaction; and that the digestive and assimilative organs be able to take up a fair amount of nourishing material, which is required by the increased demand on the body.

Acute febrile diseases.—Among the oldest therapeutic uses of the cold bath, though it has only lately been more extensively revived, is the employment of different forms of cold baths in acute febrile diseases, attended by a high degree of pyrexia. The moderately cold, or the cooled-down bath, is the form principally employed; but cold effusions, the shower-bath, the wet envelope frequently changed, cold compresses, the application of ice, washing with iced water, and iced enemata, are likewise applicable; and the liberal internal allowance of cold water forms an important part of the dietetic management of this class of diseases. See FEBRIFUGES.

Typhoid fever.—Typhoid fever is the disease in which this treatment, with numerous modifications, has been most generally adopted. As soon as the temperature of the patient reaches $102^{\circ}2'$ to 103° F., he is placed in a bath of about 90° F., and the temperature is gradually cooled down, by the addition of cold water, to 80° or 60° F., according to the patient's power of reaction. The patient is kept in the bath generally from 10 to 15 or 20 minutes, when slight shivering often manifests itself. The patient's temperature, measured in the rectum, is usually reduced by this procedure about $1\frac{1}{2}^{\circ}$ to 5° F., not immediately, but within the first hour after the bath. As often as the temperature may again reach $102^{\circ}2'$ to 103° , the patient is again placed in the bath. Thus, during the height of the pyrexia three to five baths may be required in twenty-four hours, while later on about two are usually sufficient, and often only one. Instead of the bath gradually

cooled down, a bath of a temperature between 60° and 90° F. may be given, according to the condition of the individual patient. The frequent and careful use of the thermometer is an essential element in this method of treatment, which may be, as it often is, advantageously combined with the administration of alcohol, quinine, and other remedies. The earlier the baths are commenced, the greater seems to be their influence in mitigating the severity of the disease and its sequelæ, and in shortening its duration. It is claimed that the mortality is considerably less with this than with the expectant or any of the other usual modes of treatment.

Hyperpyrexia.—A still bolder use may be made of the cold-water treatment in those rarer cases of hyperpyrexia occasionally occurring in the course of rheumatic fever, when the temperature rises to 108° F. and more; and where very cold and prolonged baths, the application of ice-bags, &c., appear to be the only means of saving life. The same treatment is likely to be useful in some forms of sunstroke; and also in some cases of hyperpyrexia arising from other acute disease than rheumatic fever.

Scarlet fever.—In scarlet fever the writer has found warmer baths (80° to 98° F.) more generally applicable than quite cold or cooled-down baths, though in cases attended by a high degree of pyrexia and brain-symptoms these are preferable.

Hectic fever.—In hectic fever, connected with various chronic diseases, the effect of hydrotherapeutic treatment is less decided, and not yet sufficiently tested.

Digestive derangements of the most different kind, associated with *sluggish venous circulation* in the abdominal organs—conditions which may be grouped together under the term *abdominal venosity*, tendency to hæmorrhoids, to hypochondriasis, &c.—are often the objects of the water-cure, which may be useful by stimulating the physical and psychical energy of the nervous system, as well as the nutrition and tissue-change, by invigorating the skin. Habitual constipation from this cause is often relieved by the hydrotherapeutic belt. In this class of cases the common salt waters and the alkaline sulphated waters are more frequently used, and are often preferable; they may, however, be advantageously combined with judicious hydrotherapeutic treatment.

Chronic metallic poisoning may be treated in some cases with equal benefit, if there is sufficient reactive power, at cold-water establishments, as at the thermal sulphur and simple thermal spas. The external hydrotherapeutic procedures, aiming at increased perspiration and tissue-change, are in this class aided by the abundant internal use of water, in order to wash out the tissues, and especially the liver.

Skin-weakness or atony of the skin is often the cause of frequently recurring attacks of diarrhœa with neuralgic pains, of tendency to catarrh of the respiratory mucous membrane, and of rheumatism. Gently stimulating hydrotherapeutic appliances, with gradually increasing energy, are here mostly useful, unless, as in impeded convalescence, the reactive power is so reduced that the gaseous thermal salt-baths and mountain-air are preferable, while in other cases sea-air and sea-baths are successful competitors of the water-cure. See SEA-AIR; SEA-BATHS; and SEA-VOYAGES.

Hysteria.—In hysteria and hysterical affections the water-cure has obtained many good results, not by the internal use of water, but by the milder forms of baths. Functional hyperæsthesia and anæsthesia, hemicrania, spinal irritation, intercostal neuralgia, and other forms of neuralgia depending on imperfect nutrition and tissue-change, are likewise often benefited.

Organic diseases of the nerve-centres are not suitable for treatment in cold-water establishments, excepting occasionally for palliative purposes.

Rheumatism and gout.—In muscular rheumatism the original supporters of the water-cure considered their plan as infallible, but this is by no means the case. The diaphoretic methods, namely, the woollen blanket-pack and the wet sheet-envelope, often prove useful; but we know also of many failures even in good establishments. The exposure to all weathers during the cure ought certainly not to be imitated by such invalids, and the access of cold air to the wet body should be more carefully avoided than is often the case. The course must not be prolonged too much at one time, but may be repeated after an interval of months, which may be spent with advantage at sheltered seaside localities, at moderate elevations, with the help of pine-leaf baths, or at one of the gaseous thermal saline spas.

Rheumatic and gouty swellings of joints require great care in their management. The enfeebled invalid is rarely a fit object for the ordinary water-cure; but the stimulating local compress, more or less impermeable, is a useful element in the treatment of such cases.

Milder cases of *gout* may expect benefit from the usual hydrotherapeutic treatment, in so far as it aims at increased retrogressive tissue-change, and invigoration of the nervous system, especially if this treatment is associated with great moderation in the use of stimulants, and also of food in general; but local packing not rarely causes fits of gout. The more serious forms of gout are too much complicated with various defects of constitution to encourage us in recommending cold-water treatment.

Chronic affections of the skin.—In some diseases of this kind, such as prurigo, urticaria, eczema, and local perspirations, a more or less modified hydrotherapeutic treatment is an important adjuvant.

Syphilis.—The favourable results obtained in syphilis have greatly contributed to the reputation of the water-cure; but the latter is only an excellent adjuvant to medicinal treatment in these cases, in the same way as the sulphur-waters are; and many of the cures of so-called *lues* may be regarded as cures of *mercurialism*.

Catamenial irregularities are not rarely treated at hydrotherapeutic establishments. Profuse menstruation is often checked by the regular use of the cold hip-bath of short duration, namely, three to five minutes; in insufficient menses, on the other hand, warm hip-baths of ten to fifteen minutes' duration are frequently useful, combined in some cases with the wet sheet-envelope; and dysmenorrhœa is likewise occasionally treated with advantage by the partial wet sheet-envelope.

This list of morbid conditions which may be more or less benefited might easily be increased. This is not astonishing if it is considered that hydrotherapeutic treatment can be infinitely modified and adapted to the powers of the constitution; and that it may be assisted by varying hygienic, climatic,

dietetic, and medicinal influences. For we must reiterate that there does not exist any antagonism between hydrotherapeutic and other rational treatment, the former being, in fact, only part of the latter. Hence, however, it is also evident that the treatment in well-arranged hydrotherapeutic establishments ought to be under the guidance of the most intelligent physicians, just as is the case at all the best spas. Indeed the physician to such an establishment ought to be of a high class, possessing in a more than usual degree the gift of recognising all the individual peculiarities of the constitution, especially the amount of reacting power, adapting the principal remedy to every individual case, and combining other elements of treatment with hydrotherapeutic management wherever this is necessary. In the same way as we demand in suitable cases the administration of other remedies together with water-treatment in hydrotherapeutic establishments, so we must also express a wish that, apart from such establishments, hydrotherapeutic elements should be more generally combined with the usual medical treatment. For this purpose it is to be desired that well-conducted establishments should be in or near large towns, in order that persons following their usual occupations might undergo certain kinds of treatment at such establishments, or that attendants from such establishments might be sent to the houses of invalids.

HERMANN WEBER.

HYDROTHORAX (ὕδωρ, water; and θώραξ, the chest).—Dropsy of the pleura. See PLEURA, Diseases of.

HYÈRES, France.—Town three miles from the sea. Mean winter temperature, 55° F. Well sheltered; little rainfall. See CLIMATE, Treatment of Disease by.

HYGIENE (ὁγίεια, health).—The science and art which relate to the preservation of health. See PERSONAL HEALTH; and PUBLIC HEALTH.

HYGROMA, CYSTIC.—See CYSTIC HYGROMA.

HYMEN, IMPERFORATE.—See MENSTRUATION, Disorders of.

HYPÆSTHESIA (ὕπoς, under; and αἴσθησις, sensation).—Diminished sensibility of a part. See SENSATION, Disorders of.

HYPERÆMIA (ὕπερ, over or excessive; and αἷμα, blood).—Excess of blood in a part. See CIRCULATION, Disorders of.

HYPERÆSTHESIA (ὕπερ, over; and αἴσθησις, sensation).—Increased sensibility of a part. See SENSATION, Disorders of.

HYPERALGESIA (ὕπερ, over; and ἄλγος, pain).—Undue sensibility of a part to painful impressions. See SENSATION, Disorders of.

HYPERIDROSIS (ὕπερ, excessive; and ἰδρῶς, sweat).—Excessive perspiration; also termed *hidrosis*, *ephidrosis*, and *sudatoria*. See SUDORIPAROUS GLANDS, Diseases of.

HYPERINOSIS (ὕπερ, over; and ἵς, ἰνός, flesh).—Excess of fibrin in the blood. See BLOOD, Morbid Conditions of.

HYPERMETROPIA (ὕπερμετρος, beyond measure; and ὥψ, sight).—A congenital or acquired error of refraction of the eye, in which, owing to low refractive power of the dioptric media, or too little convexity of the refracting surfaces, or unnatural shortness of the antero-posterior axis of the eyeball, parallel rays of light do not, while the accommodation is in repose, converge to a focus on the layer of rods and cones of the retina, as in the normal or emmetropic eye, but to an imaginary point somewhere behind. It is the opposite of myopia, and is sometimes called hyperopia or hyperpresbyopia. See VISION, Disorders of.

HYPEROPIA (ὕπερ, above; and ὥψ, sight).—See HYPERMETROPIA.

HYPERPLASIA (ὕπερ, over; and πλάσσω, I mould or form).—An excessive growth of normal tissue-elements, which may lead to hypertrophy, or to the formation of distinct tumours. See HYPERTROPHY; and TUMOURS.

HYPERPRESBYOPIA (ὕπερ, above; and πρέσβυς, old; and ὥψ, sight).—See HYPERMETROPIA.

HYPERPYREXIA (ὕπερ, excessive; and πυρεξία, fever).—Excessive pyrexia. See FEVER; TEMPERATURE; and HYDROTHERAPEUTICS.

HYPERTRICHOSIS.—See HAIR.

HYPERTROPHY (ὕπερ, over; and τροφή, nourishment).

DEFINITION.—The word 'hypertrophy' signifies excessive nourishment, but is in practice used to designate the result of excessive nourishment—that is, excessive growth. It must be carefully distinguished from mere enlargement, and only spoken of where there is a real increase in a part, or, at least, in a tissue, without alteration of quality. Hypertrophy may be *general* or *partial*.

I. General Hypertrophy.—General hypertrophy, though a remarkable condition, is of little practical importance. It is known only in those individuals of enormous size who are called 'giants.' The production of giants depends on causes entirely unknown, since it is noticeable that this condition commonly affects only one in a family, and is in its most conspicuous forms not hereditary. Giants are usually of feeble constitution, and deficient in procreative power. The name *macrosomatia* has been given to a condition equally unexplained, in which the whole body becomes enlarged in a monstrous degree. This condition has been observed to be in some instances congenital, or, at least, to begin in very early life. True general hypertrophy does not appear to be capable of being produced by any artificial means, since excessive feeding either produces hypertrophy almost confined to one tissue—namely, fat—or else fails to produce any enlargement at all.

II. Partial Hypertrophy.—By this is meant (a) excessive increase of any part or tissue of the body during the period of natural growth, either in intra-uterine or extra-uterine life; or (b) increase of a part or tissue already completely formed. According to this distinction hypertrophy may be classified as either (1) *congenital* or (2) *acquired*.

I. CONGENITAL HYPERTROPHY.—Congenital hypertrophy is that condition in which some part of the body begins from the first to grow so rapidly as

to attain a size far beyond the normal. This condition has been seen to affect one side of the body, or one limb only, which thus becomes much larger than its fellow on the other side. Such a condition might be in theory difficult to distinguish from atrophy of the opposite side, or of the other limb—that is, from hemiatrophy (see ATROPHY); but in general the hypertrophic side is so far beyond the normal size as to prevent ambiguity. One remarkable case is on record in which one leg and arm assumed the proportions of those of a giant, while the other remained unaltered. Sometimes a congenital hypertrophy occurs without this unilateral character, as in the case reported by Curling of a girl aged fifteen, who had several fingers of both hands enlarged in an extraordinary degree without any assignable cause, the equality of the two sides being nevertheless preserved. The whole head, or one side of the head, may become abnormally enlarged. Such instances, although unexplained, must, it would seem, be put into the same class as the gigantic growth of the whole of the body. Hypertrophy of special tissues is also sometimes congenital, as of the skin in Ichthyosis. Congenital hypertrophy of the hairs is known as Hypertrichosis; that of the nails as Hyperonychchia. Congenital overgrowth of bones is also observed, forming congenital Hyperostosis, or, as affecting the face, Leontiasis ossea. Hypertrophies similar to those here called congenital may occur, though rarely, in adult life. The enlarged part is found to be highly vascular, to have an increased temperature, and to preserve its normal proportions. The cause is in these cases equally unknown.

2. ACQUIRED HYPERTROPHY.—Acquired hypertrophies may be classified as follows:—

(a) *Recuperative*, consequent on increased work.
(b) *Defensive*, arising from pressure or inflammation.

(c) *Nutritive*, from increased supplies of food.
(d) *Apparently spontaneous* or of unknown cause.

(a) *Recuperative*.—Some organs and tissues are so constructed that increased functional activity causes hypertrophy. This is especially the case with the muscles. It is a matter of familiar observation that voluntary muscles increase in size when much employed, as is seen in the often-mentioned arm of the blacksmith or the leg of the ballet-dancer. In order to produce this increase, the exercise must be of a certain degree of intensity, but not excessive. It must be frequently repeated, with intervals of rest; and at the same time the nutrition of the whole body must be good. In the absence of these conditions, exercise is more likely to produce wasting. The explanation of this familiar process is still obscure.

Hypertrophy of the heart occurs in cases where that organ is made to work at a higher tension than the normal, and this higher tension can only result from increased resistance to the flow of blood, either at one of the orifices of the heart, or in the peripheral vessels. Hence the conditions most commonly giving rise to it are valvular disease, especially stenosis; and obstruction of the arteries, either by the thickening of their walls, or by contraction of their muscular coats. The right side of the heart will also become hypertrophied when any condition whatever hinders the passage of blood through the lungs. Disease of the kidneys is a frequent cause of hypertrophy of the left ventricle of the heart, though in what way is still a matter of discussion.

It is only quite clear that the kidney-disease in some way increases the resistance in the smaller arteries and capillaries of the body generally.

Hypertrophy of the smooth or involuntary muscular fibres also occurs whenever that tissue has to contract for a long period under a higher tension than the normal. Thus the walls of the bladder become thickened in cases where, from obstruction of the passages, the evacuation of urine is effected with more difficulty, and under a higher pressure, than usual. In the same way the walls of the stomach, the œsophagus, and the intestines become hypertrophied in cases of obstruction to the passage of food through the alimentary canal.

The explanation commonly given of these cases of hypertrophy in the contractile organs is a teleological one, that in consequence of obstruction the organ *has* to contract with greater force than usual, and thus becomes hypertrophied in the same manner as a voluntary muscle which is frequently exercised. It is, however, clear that this so-called explanation does not account for the connection between obstruction and more powerful contraction. The only explanation that can be given is that in these cases pressure or tension on the organ itself is the stimulus to contraction, and that the force of contraction appears to depend roughly upon the strength of the tension which produces it.

There is less evidence that nervous or glandular structures undergo hypertrophy in consequence of their increased use; but if one kidney be destroyed the other is generally found enlarged; and some authorities believe in an increase in the size of the brain from mental activity.

(b) *Defensive hypertrophy* is the natural reaction of certain tissues against slight injury or irritation, whereby they become increased and serve the purpose of protection. But if the injury be excessive, atrophy or destruction of tissue results.

Pressure, which is a mild form of irritation, produces, when moderate and intermittent, hypertrophy of the external integument; but some regions of the skin are much more affected by this cause than others. It is difficult to draw the line between this and inflammation.

Inflammation does not cause hypertrophy of organs generally, but only of the connective tissues. In most tissues, e.g. muscular, nervous, glandular, the only result of inflammation is atrophy or destruction, with loss of functional power. But it seems to be a general law that moderate inflammation, chronic or intermittent, causes connective tissue to increase. Purely fibrous structures, such as serous membranes, become thickened by chronic or repeated inflammation of moderate intensity, especially if supuration be not produced, but this increase is not always permanent. In periostitis the formation of new bony tissue causes the increase to be permanent, and thus hypertrophy of bone is a frequent consequence of inflammation. The increase of connective tissue from irritation is obviously a conservative or defensive process, placing a barrier to the extension of injurious agents, and forming a capsule round foreign bodies.

Increase of connective tissue is also constantly present in chronic interstitial inflammation of solid organs, where indeed it is often impossible to draw the line between inflammation and fibrous overgrowth, and the term Inflammatory Hypertrophy has been used. These changes are produced by some irritation or injury, or result from wasting of

the other (parenchymatous) elements of the organ. In consequence of this atrophy of the other tissues there is likely to be rather a diminution than an increase in the size of the organ or part generally.

(c) *Nutritive hypertrophy*.—It must be regarded as doubtful whether increased nourishment alone is capable of producing enlargement of any part of the body. It certainly does not necessarily do so, as is shown by the case of experimental hyperæmia, produced, for instance, by section of the cervical sympathetic nerve, in one side of the face and head of an animal, when hypertrophy is only a rare and occasional consequence. When, however, the increased supply of nutrition in the form of blood is combined with some irritation or functional stimulus, we often find hypertrophy result. Thus, for instance, reflex hyperæmia of the skin of the face, or blushing, which is produced by numerous internal causes, such as gastric or uterine derangement, may subsist for years and reach a very high degree without altering the nutrition of the part. But if there should be in addition some disturbance or inflammation of the glands of the skin, we have the condition called *acne rosacea*, in which hypertrophy is an important element. Almost the only instance that can be quoted of hypertrophy from increase of blood-supply alone is that of the corpus luteum during pregnancy, when the ovary participates in the functional hyperæmia of the uterus. The well-known experiment of Hunter should also not be forgotten, in which he transplanted the spur of a cock from its foot to its head, and found it to increase in size.

Special nutrition.—It is well known that abundant supplies of amylaceous and fatty food, especially with a full allowance of water, cause increase of the adipose tissue. It is also said that small doses of phosphorus favour the growth of bone in young animals. But there is no other instance in which it is known that any special food causes hypertrophy of any special tissue.

(d) *Apparently spontaneous or physiological hypertrophy*.—Physiological hypertrophies form an important class. One of the best instances is that of the enlargement of the uterus during pregnancy. This enlargement is clearly not the consequence of hyperæmia alone, nor of increase of the functional activity in the muscular walls, though both these conditions are present; but must proceed from some direct physiological stimulus like that which determines the growth of the embryo itself. The hypertrophy affects all parts of the organ—its mucous and serous coats, as well as the muscular walls. Enlargement of the mammæ appears to arise from similar causes; and it is even probable that swelling of the thyroid gland may, through some obscure connection with the sexual organs, be caused in the same way. Some instances of hypertrophy we cannot in any way explain, such as the apparently spontaneous enlargements of the tonsils, spleen, and thymus gland which are sometimes observed. *Acromegaly* is a form of partial hypertrophy. A peculiar hypertrophy, with deformity of the extremities, associated with pulmonary disease, has been called by Marie ‘pulmonary hypertrophic osteoarthropathy.’ See *ACROMEGALY*.

Process of Hypertrophy.—It has been a question whether hypertrophy depends upon the increase in the size of the minute elements of an organ, or only on increase of their number. There can be no doubt that the former change often

occurs. Thus, in the pregnant uterus the muscular fibres have been found from seven to eleven times as long as natural, and from twice to seven times as wide. In a remarkable case of enlargement of the nerves, described by the late Dr. Moxon, the nerve-fibres were found to be on an average three times and some of them even forty times as large as normal. When enlargement of one kidney takes place as a consequence of destruction of the other, the tubules and Malpighian tufts are found greatly increased in size. In hypertrophy of the heart, the muscular bundles are found to be thickened, though the fibrillæ are unchanged; but in most cases multiplication of the tissue-elements is the chief cause of the increase in size. To this latter process Virchow gives the name of *hyperplasia*, and it is important to remember that, though constantly occurring in hypertrophy of organs, it does not necessarily lead to the latter change.

'False' Hypertrophy.—The term *false* hypertrophy is sometimes used for a process in which an organ becomes outwardly increased in size, owing to the deposition within it of some foreign material, or to mere distension, as in a fatty liver, an emphysematous lung, or a hydrocephalic brain. The disease called 'Duchenne's pseudo-hypertrophic paralysis' is another instance. But the term is hardly needed, except as a caution.

TREATMENT.—It is obvious that no general rules can be laid down for the treatment of hypertrophy. When it is connected with increased functional activity, it is usually a favourable rather than a hurtful condition, though in some cases it may appear that the hypertrophy more than compensates the deficiency or irregularity by which it is produced. But even if this be so, the cure of excessive hypertrophy is not within our powers. The utmost that can be done is to endeavour, if possible, to check the process by which the hypertrophy is produced. Functional hypertrophy, however, which has resulted from some obstacle or undue resistance, may entirely subside when that resistance is removed. Thus if the uterus have enlarged around a fibrous tumour, it may regain its normal bulk when the tumour is removed; and we sometimes see a sensible diminution in the size of an hypertrophied heart when the derangements which produced it no longer act. Moreover, hypertrophy may be completely reduced by a general lowering of the nutrition of the body. Thus, in early stages of pulmonary phthisis, the heart may be hypertrophied; but when death occurs in a late period of the disease, the organ is rarely found enlarged, and is even wasted; though according to Peacock's tables, less so than in other wasting diseases.

J. F. PAYNE.

HYPINOSIS (ὑπός, under; and ἴς, *ivós*, flesh).—Deficiency of fibrin in the blood. See BLOOD, Morbid Conditions of.

HYPNOTICS (ὑπνος, sleep).—Measures or agents employed to induce sleep. See NARCOTICS.

HYPNOTISM (ὑπνος, sleep).—A synonym for Braidism. See BRAIDISM; and MESMERISM.

HYPOCHONDRIASIS (ὑπό, under; and χόνδρος, a cartilage).—SYNON.: Fr. *Hypochondrie*; Ger. *Hypochondrie*.

DESCRIPTION.—The term 'hypochondriasis' is derived from an ancient hypothesis that the sym-

ptoms of this disorder were due to perturbations of natural force generated in the liver and pylorus, to which idea the frequent prevalence of flatulence probably conduced. The condition thus called is really a disease of the nervous system. It is a form of mental unsoundness closely allied to melancholia, of which, indeed, it often forms the initial stage. It is characterised by a morbid anxiety, either without any, or having only very slight foundations, relative to the state of physical health. The patient thinks about his health unduly, observing himself with restless care, examining especially the characteristics of his secretions, translating into evidence of progressive organic mischief every trivial departure from perfect action of his organs, and becoming more and more absorbed in precautions against the malady with which he believes himself affected. Nothing that happens tends to the side of reassurance. If his sleep be disturbed, the symptom may be portentous, he thinks, of brain-softening; if it be sound, the patient, instead of being comforted, fears apoplexy. Constipation of the bowels signifies obstruction; a slight diarrhoea implies coming exhaustion. Everything which he reads or hears in reference to disease the patient applies to his own case, examining himself on every point thus presented to his mind, and rarely failing to find something which dovetails with symptoms of his own. For he recognises only the points of resemblance; the features of difference are unconsciously ignored. In some cases the patient is constant in referring his troubles to one particular organ. Year after year his story is the same: it is his stomach, liver, brain, or some other organ, which is in fault; but always the same. In other instances there is a vacillation quite as remarkable. Routed, perhaps, by the convincing arguments of his adviser, he is forced to yield the position which he had assumed, but only to take an equally strong one in reference to some other part of his frame. These diversities strongly recall the fixed and shifting delusions of insanity. The patient is prone to wander from one doctor to another, often carrying with him a bundle of prescriptions and a long written list of questions, which must receive categorical answers. Apparently satisfied at the time, he speedily recollects some point upon which he has not received assurance, and this, he conceives, vitiates the whole of the explanation and advice which have been given to him, and he is plunged again into his previous state of anxiety and doubt. Where circumstances do not involve forced labour for existence, the patient passes his time in chasing his health, which is always contriving to elude his grasp. If he holds an appointment, he will resign it in order to have full opportunity for studying himself; and, his occupation once gone, he finds too late that it was his best friend, and he then ascribes to his forced idleness all the ills which had induced him to seek retirement.

In many cases the most careful examination can discover no signs of disease, and the patient wears the aspect of health; or there may be a worn, anxious look. In others there may be, especially in the digestive organs, slight deviations from perfect integrity, which explain some of the symptoms, but not the exaggerated apprehensions to which they give rise.

Hypochondriasis is a chronic disorder. It may continue, and this perhaps most frequently, as a

harmless peculiarity attached to a life which is not perceptibly shortened in length, though often sadly diminished in utility and happiness, by its symptoms. Or there may be an improvement practically amounting to a cure, which will endure for a longer or shorter period. In the decline of life, however, there is very apt to be a return of symptoms, which are often then much exacerbated. Or hypochondriasis may pass into true melancholia, and then the bodily health, previously the constant object of solicitude, improves wonderfully. Indeed, nothing more is heard about it.

ÆTIOLOGY.—Hypochondriasis is very much more common in the male than in the female sex. The period of life most prone to it is from 20 to 40 years of age. It is apt to occur in those who inherit a tendency to insanity, and the disease in its own peculiar form is often hereditary. Excesses of various kinds, especially on the side of the sexual system, will precipitate the appearance and intensify the symptoms of the affection, but it is doubtful whether they can altogether originate it. The same may be said of gout, which is apt to be associated with the condition, and to complicate its symptoms. Depressing moral circumstances also are not without influence in determining an onset of hypochondriasis in those predisposed to it. This is especially true of mental strain. The frequent occurrence of some deviation from healthy condition in the liver, stomach, or bowels, which is noted in these cases, would suggest that, probably through an interruption to the perfect nutrition of the body, diseases of these viscera bear their part in the causation of hypochondriasis. The intercurrent occurrence of internal hæmorrhoids with bleeding is very common, and this would manifestly tend to keep up, if it did not originate, the disease. Stricture and chronic ulcer of the intestines are occasionally associations which probably also influence the appearance of hypochondriasis.

ANATOMICAL CHARACTERS.—There are no anatomical characters peculiar to the disease.

DIAGNOSIS.—When careful examination, which must never be omitted, has disproved, so far as is possible, the existence of organic disease tending to produce the symptoms described by the patient, it sometimes becomes a question whether the case is one of hypochondriasis or of melancholia.

In the former there is no tendency to suicide; on the contrary, a strong desire to live pervades the sufferer's mind, and impels him to endless search for the cure of his ailments. He delights in consulting medical men and entering into the minutest details which he thinks can aid them in helping him. Up to a certain point his story is frequently characterised by a logical accuracy, which fails him, however, in some point of great importance, by which the conclusions are invalidated. The melancholic patient, on the other hand, is often suicidal and always despairs of any relief to his condition, the description of which, as given by him, is confused, frequently incoherent, and unintelligible. *See* MELANCHOLIA.

PROGNOSIS.—Early and marked hypochondriasis occurring in a person with a strong hereditary taint of insanity, without any definite cause of mental depression, is of ill omen. Such a case very often drifts into pronounced melancholia.

The prognosis is more favourable, perhaps, the less strongly marked the hereditary predisposition and the more evident and adequate the immediate

causes to which the patient has been exposed, the most potent of which are sexual or alcoholic excesses, mental strain or shock, or the sudden change from a life of activity to one of forced, and, as the sequel shows, uncongenial leisure.

TREATMENT.—Moral treatment alone is of any influence in a large majority of cases. When there is, however, manifest anæmia, a history of syphilis, evidences of gouty mal-assimilation, accumulation of fæces, catarrh of the intestinal canal, or hæmorrhoids, the therapeutics proper to these conditions should be employed. Alcoholic stimulants should be avoided. Travel, especially under judicious companionship, and the encouragement of regular, definite, and useful employment for the attention and the physical powers, are the most potent means of treatment, by which the disease may be often much ameliorated, and sometimes cured. Ridicule of the patient's sufferings will rarely or never be of service, but at the same time a habit of prescribing for all the symptoms as they arise must be avoided.

T. BUZZARD.

HYPOTHERMIC MEDICATION (*ὕπὸ*, under; *δέρμα*, the skin).—**SYNON.** : Fr. *La méthode hypodermique*; Ger. *Hypodermatische Injection der Arzneimittel*.

DEFINITION.—The introduction, by means of a sharp-pointed hollow needle, of various drugs into the subcutaneous cellular tissue.

METHOD OF APPLICATION.—The needle, which must be sharp and smooth at its point, should always be *sterilised* either by holding it in the flame of a spirit-lamp for a few seconds, or by immersing it in boiling water. It is a good plan both before and after use to fill and empty the syringe several times with a hot solution of one in twenty carbolic acid. If a hypodermic tablet is used, it should be dissolved in a syringeful of sterilised water; if, on the other hand, a ready-made solution of the drug is used, the dose to be administered should be accurately gauged by moving down the button to the required mark on the piston. Both methods guard against the possibility of overdosage. A fold of skin is pinched up, or otherwise stretched, between the left thumb and index-finger, the needle is pushed firmly and sharply into the cellular tissue, and the barrel of the syringe being steadied between the right index and middle fingers, the fluid is slowly injected by pressure with the right thumb on the end of the piston. This method is generally painless or nearly so. The proceeding is modified in certain cases. Thus, ergotin should be injected deeply into the muscular tissue; and, in some instances, cocaine is injected into the cutis vera (*see* ANÆSTHESIA, LOCAL). *Local ill-effects*, such as pain, abscess, bleeding, and ecchymosis, are almost always avoidable with proper precautions. Except in some rare instances, only parts with abundant subjacent cellular tissue should be selected. Such parts as the face, forehead, and ears, as well as the neighbourhood of large vessels, are to be avoided. *General ill-effects* may arise from injections, especially of narcotics, in diabetics, alcoholics, and the subjects of renal disease. *Solutions* should be made with vehicles which fulfil the following conditions: (1) They should have a high solvent power. (Some drugs, however, can only be administered in a state of suspension.) (2) They should be permanent, not deteriorating by keeping. (3) They should be non-irritating. Carbolic acid or boric acid may often

be added to the solution with advantage. Paroleine is the best vehicle for the injection of carbolic acid, eucalyptol, iodoform, and turpentine. Solutions should be kept in glass-stoppered bottles, or hermetically sealed glass capsules. Soluble tablets are both convenient and portable.

INSTRUMENTS.—For general purposes a simply constructed and accurately graduated syringe with a capacity of twenty minims should be used. It should be adapted to an aseptic metal case with two or more needles, and a supply of silver wires to keep their canals clear. The needles, which should be sharp and smooth at the point, may be made of nickled steel or gilded platinum. The weakest part of the needle is just at the shoulder, and this should always be carefully examined before use. By an ingenious contrivance the needle may be passed through the shoulder before the latter is screwed on to the nozzle of the syringe, and any defect is thus quickly and easily remedied. Drying and consequent shrinking of the piston-packing may be obviated by a metal cap which is applied to the nozzle after using the syringe. An instrument not in frequent use may easily be kept in good condition by occasionally washing it out with hot carbolic water. Where the barrel consists of glass, the metal parts should never be attached by cement. Some makers manufacture the syringe entirely of metal. The minims are best marked on the *piston*, which should have a screw-thread on which a button runs. In this way the dose can be accurately gauged and fixed before the injection is made. The piston, which should have a simple sliding, not a screw-action, is terminated at the top by a flat knob which is pressed by the thumb when the injection is made. In some cases, as in the injection of alcohol, ether and saline solutions, syringes of larger capacity may be used to avoid multiple injections. From time to time the instrument should be boiled.

ADVANTAGES.—These are obvious, but the method has its limitations. The hypodermic injection of such drugs as morphine and cocaine should always be under the direct control of the practitioner, and ought never to be entrusted to the patient or the friends. As compared with other modes of drug-administration, the advantages of the hypodermic may be briefly summed up as follows: (1) Greater rapidity of absorption and more speedy effect as in the relief of pain, and the production of vomiting, or rapid stimulation; (2) a strictly local effect as in the injection of cocaine or β -eucaine (see **ANÆSTHESIA, LOCAL**); (3) an efficient method of administration when other methods are impossible—e.g. cases of vomiting, nausea, and other conditions due to an irritable or diseased stomach, cases of dysphagia, and certain cases of delirium, mania, or coma; and (4) less risk of a cumulative effect (Eulenburg).

REMEDIES USED HYPODERMICALLY, AND DISEASES FOR WHICH THEY ARE EMPLOYED:—

Acidum Benzoicum.—Benzoic acid, 10 grains; alcohol, to 112 minims. *Dose*, from 8 to 16 minims. (The solution should be slightly warmed before use.) *Used* as a respiratory stimulant in the collapse of acute fevers, and in uræmia.

Acidum Carbolicum.—Pure carbolic acid, 1 or 2 grains; paroleine, or water, to 112 minims. *Dose*, 8, 16, or 24 minims. *Used* in erysipelas, malignant pustule, and other infective diseases.

Aconitina.—The B.P. preparation should be employed. Aconitine, 1 grain; dilute sulphuric acid,

q.s.; distilled water, to $\frac{1}{2}$ ounce. (Martindale.) *Dose*, 1 or 2 minims. The first dose should not exceed $\frac{1}{100}$ grain. It has been *used* in various forms of neuralgia, especially of the trigeminal, and in various other diseases, but in most cases the use of the Tinct. Aconiti *per os* is preferable.

Æther.—Sulphuric ether is the best form for hypodermic use. It may be employed alone, in combination with alcohol, or with camphor (1 in 10). *Used* in cases of collapse, whether arising from injury or disease.

Alcohol, in doses of 30 to 60 minims, in the form of whisky or brandy, may be *used* for the same purposes as ether, by deep injection.

Ammonia, Liquor.—*Dose*, 2 to 5 minims hypodermically or intravenously. Of great value in syncope from any cause, and in threatened death from embolism. See **SALINE SOLUTIONS**.

Amyl Nitris.—Nitrite of amyl, 1 part; alcohol, 9 parts. *Dose*, 8 to 12 minims. *Used* in threatened death during chloroform anæsthesia, in strychnine-poisoning, and, especially, in angina pectoris.

Antipyrine, in doses of from 4 to 5 grains, cautiously increased, in fresh aqueous solution. *Used* in various neuralgias and to relieve the pains of tabes dorsalis. It should be injected along the course of the hyper-sensitive nerve. The first effect is painful, but the resulting anæsthesia often lasts for several days.

Apomorphine Hydrochloridum.—*Dose*, 5 to 10 minims of the freshly prepared B.P. solution, or tablets $\frac{1}{15}$ to $\frac{1}{10}$ grain. An over-dose may kill by causing profuse bronchial secretion (Lauder Brunton). *Used* as a prompt emetic.

Aqua.—Iced water has been used hypodermically with some success for the relief of pain (e.g. sciatica) and to reduce pyrexia. Hot water has been also used for localised pain over a limited area. But the most important method is that which is known as *Hypodermoclysis*—the '*injections massives*' of French authors. Sterilised water containing some saline, or salines, in weak solution is employed at a temperature of 100° F. The following is a useful formula: Sodium chloride, 1 drachm; boiled water, 1 pint. One to three pints of this solution may be injected 3 or 4 times daily. The apparatus required consists of a glass receiver from the lower end of which a tube leads to a fine trocar. The skin at the point of puncture (the lumbar, gluteal, scapular, or submammary region) having been sterilised, and the apparatus also rendered aseptic, the needle is pushed steadily and quickly into the cellular tissue, and the fluid is allowed to flow in slowly and evenly, the rate of influx being regulated by the height at which the receiver is placed. Diffusion and absorption may be facilitated by occasional gentle massage. When the needle is withdrawn collodion is applied to the puncture. Direct injection into the veins has been recommended and practised (see **SALINE SOLUTIONS**), but, as a general rule, the hypodermic method is preferable on account of its absolute safety.

Hypodermoclysis is invaluable in various forms of hæmorrhage, in shock, and in septic conditions of the blood. It is thus used in uræmia, septicæmia, and diabetic coma; also in the collapse of cholera and in peritonitis. In cases of urgency, when the apparatus is not at hand, rectal saline injections may be used in the first instance. Intraperitoneal saline injections have also been used successfully.

Arsenium and its preparations.—Great care is

necessary to prevent local irritation. Fowler's solution, 1 part; distilled water, 2 parts, may be employed. *Used* in various nervous and cutaneous diseases and in septic conditions. Recommended by Jaccoud and others in tubercular affections. See SODII CACODYLAS, under this article.

Atropina.—Neutral sulphate of atropine, 1 grain; distilled water, to 2 ounces 160 minims. *Dose*, 8 minims ($\frac{1}{150}$ grain). The solution must be freshly prepared. Tablets $\frac{1}{150}$, $\frac{1}{100}$, $\frac{1}{60}$ grain, dissolved in hot water, are useful. *Used* as an antisudorific and antispasmodic; also as an analgesic, especially in combination with morphine.

Auri Chloridum.—*Dose*, $\frac{1}{35}$ grain in 20 minims of distilled water. *Used* in some syphilitic affections, also to cure (?) the alcohol-habit.

Caffeina.—Caffeine, 20 grains; sodium salicylate, $17\frac{1}{2}$ grains; distilled water, to 1 drachm (3 minims = 1 grain). *Dose*, 1 to 6 minims (Martindale and Westcott). *Used* in various nerve-pains, chronic alcoholism, cardiac dropsy, and in poisoning by alcohol, opium, and cocaine.

Calabarina, *Physostigmatis Extractum*. *Calabarina*, *Extract of Calabar Bean*.—The latter is best adapted for hypodermic use. Extract of Calabar bean, 10 grains; rectified spirit, 10 minims; rub together till smooth, and add gum acacia, 10 grains; mix, and add gradually distilled water to half an ounce. *Dose*, 3 to 12 minims. *Eserine* salicylate, $\frac{1}{100}$ grain, may also be employed. *Used* in tetanus, strychnine-poisoning, and enuresis.

Chloroformum.—*Dose*, 10 to 20 minims. Rarely *used* as a substitute for morphine in various painful affections.

Cocaina.—*Dose*, 2 to 5 minims of the B.P. solution, or tabloids of $\frac{1}{6}$, $\frac{1}{4}$, or $\frac{1}{2}$ grain. Chiefly *used* to produce local anaesthesia, either alone or in combination with morphine according to Schleich's method (see ANÆSTHESIA, LOCAL). Cocaine has also been used for the relief of megrim, hemicrania, and other nervous affections, as well as to overcome the craving for morphine and alcohol. It must be used with caution. See HABITS.

Codeina.—The phosphate may be used in *doses* of $\frac{1}{8}$ to $\frac{1}{4}$ grain in 20 minims of distilled water. *Used* mostly in diabetes mellitus.

Conina.—The hydrobromate in *doses* of $\frac{1}{20}$ to $\frac{1}{5}$ grain has rarely been *used* in various spasmodic nervous affections.

Curara.—Best administered hypodermically and in *doses* of $\frac{1}{12}$ grain. *Used* in tetanus and hydrophobia.

Digitalinum.—*Dose*, $\frac{1}{100}$ grain in 20 minims of distilled water. *Used* very exceptionally hypodermically.

Ergotininum.—Ergotinine citrate in *doses* of $\frac{1}{200}$ to $\frac{1}{100}$ grain in hot aqueous solution may be used, or 3 to 10 minims of the Injectio Ergotæ Hypodermica, B.P., may be given. *Used* in uterine hæmorrhage, hæmoptysis, and other hæmorrhages. It should be injected deeply.

B-Eucaine Hydrochloride.—A synthetic substance closely allied to cocaine, is soluble 1 in 20 of water. It is less toxic than cocaine, and does not affect the pupils. *Used* to produce local anaesthesia. See ANÆSTHESIA, LOCAL.

Ferri Ammonio-citras.—*Dose*, 2 grains and upwards. Rarely *used* in anaemia.

Gelatinum.—Has been used with success in some cases of aneurysm and hæmophilia. Its use is dangerous when there is kidney trouble. *Dose*,

six to eight ounces of a sterilised solution injected into the gluteal region twice or thrice weekly. See ANEURYSM.

Hydrargyrum.—*Mercury* and its salts. Mercury should only be used hypodermically in very exceptional cases, e.g. in grave and rapidly progressive syphilitic visceral lesions, and to overcome obstinate local syphilitic affections. It must always be avoided in dyscrasic conditions, as well as in renal disease, diabetes mellitus, and atheroma. Bacelli's method may be used of injecting 20 minims of a 1 per cent. solution of the cyanide every day or every other day till the desired effect is produced, or the plan of Lang of Vienna, which is claimed to be unirritating, may be adopted. Lang uses a 50 per cent. mixture of metallic mercury with fat and oil, which he calls 'grey oil.' The mixture is warmed to a temperature of 23° or 24° C. before use, and 0.05 c.c. (= 0.04 gramme of mercury) is injected twice weekly till improvement sets in, and then every 5 or 8 days until there is apparent cure. After this, two injections at intervals of 10 to 14 days are given as supplementary treatment. Eight to twelve injections in all generally suffice.

Hyoscina and its salts.—The hydrobromide in *doses* of $\frac{1}{200}$ to $\frac{1}{75}$ or $\frac{1}{50}$ grain in aqueous solution should be employed. *Used* to quiet excitement and induce sleep, especially in maniacal cases, in puerperal mania, and in the insomnia due to worry. It is only temporarily useful in paralysis agitans. It may be used as an antispasmodic and antisudorific. It is not an analgesic.

Morphine Tartras.—Other salts may be used, but this is the least irritating. *Dose* of the Injectio Morphine Hypodermica, B.P., 2 to 5 minims. Morphine may be combined with cocaine (see ANÆSTHESIA, LOCAL) or with atropine. It is used for the relief of pain, to induce sleep, to arrest nervous vomiting, and in the treatment of some forms of diabetes mellitus. It is unsafe in structural disease of the kidneys. Great care must be taken to avoid inducing the morphine-habit. See MORPHINE-HABIT, p. 611.

Muscarina is similar in its action and uses to pilocarpine, over which it possesses no advantage.

Nitroglycerinum or *Trinitrin*.—Tablets of $\frac{1}{250}$ grain dissolved in distilled water; to be injected deeply. Of great value in anginal attacks, especially when these are due to double aortic disease. In these cases where there is insomnia and feeble cardiac action a combination of trinitrin $\frac{1}{250}$ grain, morphine $\frac{1}{4}$ grain, and strychnine $\frac{1}{10}$ grain, affords great relief. Trinitrin is also used in some forms of asthma and in sea-sickness.

Pilocarpine Nitras.—*Dose*, $\frac{1}{10}$ up to $\frac{1}{2}$ grain. *Used* as a powerful diaphoretic.

Quinina.—The hydrobromide or the hydrochloride may be used in *doses* of $\frac{1}{2}$ to 1 grain dissolved in hot water 20 minims.

Sodii Cacodylas.—This is obtained from Cacodyl, one of the series of compounds formed by arsenic with alcohol-radicles. Cacodylate of sodium, which contains 55 per cent. of arsenious acid, is best administered hypodermically, and in this way it has a much wider range of action than arsenic. Further, its use is not attended with pain, and it is less likely to disturb the system. Gauthier recommends the following formula: Sodium cacodylate, 6.40 grammes; carbolised alcohol, 10 drops; and distilled water, 100 drachms. This mixture should be boiled for a few moments, and then made up to

100 drachms with distilled water. Each cubic centimetre (16 minims) contains 5 centigrammes ($\frac{3}{8}$ grain) of cacodylic acid. One dose is given every day for 8 or 10 days, and then an interval of 8 or 10 days is allowed. The drug is very useful in tubercular diseases, in some cases of diabetes mellitus, in exophthalmic goitre, and even in leucæmia. It is useful also as a palliative in cancer of the stomach. It must not be used where there is hæmorrhage.

Sparteine Sulphate.—Dose, $\frac{1}{10}$ to $\frac{1}{2}$ grain. A useful substitute for digitalis as a cardiac tonic.

Strophanthin is very rarely used as a cardiac stimulant and tonic.

Strychnina.—The hydrochloride in doses ranging from $\frac{1}{100}$ to $\frac{1}{30}$ grain in aqueous solution is in more or less constant hypodermic use. It is an invaluable respiratory and vaso-motor stimulant. Hence it is of great value in threatened cardiac failure, especially when due to acute pulmonary disease. It is useful in failing respiratory action due to opium-poisoning. It is of great value in various forms of paralysis.

Stypticin or Cotarine Hydrochloride is obtained by the oxidation of narcotine. It is useful in various forms of uterine hæmorrhage, but it has no influence on bleeding due to neoplasms. The dose is three grains deeply injected into the gluteal muscles, to obtain an immediate effect.

Water.—See AQUA, p. 706.

ANDREW S. CURRIE.

HYPODERMOCLYSIS (*ὕπό; δέρμα; κλύσις*, a drenching).—**SYNON.**: Fr. *injections massives*.—The hypodermic injection of artificial serum or saline solutions. See HYPODERMIC MEDICATION: *Aqua*. See also SALINE SOLUTIONS.

HYPOGLOSSAL NERVE, Disorders of.—The hypoglossal nerve is the motor nerve for the tongue, and for most of the other muscles which are attached to the hyoid bone, the exceptions being the stylo-hyoid, the mylo-hyoid, and the middle constrictor of the pharynx. It also supplies the sterno-thyroid muscle.

1. Paralysis.—Paralysis of this nerve is shown chiefly by the resulting interference with the movement of the tongue—'glossoplegia.'

ÆTIOLOGY.—The hypoglossal nerve may be damaged in any part of its course by the growth of tumours, even outside the skull; but is most commonly affected at its origin from the medulla, by pressure, meningitis, syphilitic processes, or by caries of the upper cervical vertebræ. The tongue is also paralysed by disease of the nucleus of origin of the hypoglossal fibres, but its paralysis is then associated with that of the lips, and commonly also of the palate, pharynx, and glottis (see LABIO-GLOSSO-LARYNGEAL PARALYSIS). Such paralysis may be sudden, from local softening, or gradual, from nuclear degeneration. The latter form is often part of progressive muscular atrophy, due to a similar affection of the motor structures in the spinal cord. Disease of the motor tract above the nucleus also causes paralysis of the tongue, together with the face, arm, and leg of the same side. The tongue then deviates towards the paralysed side. In disease of the left hemisphere, with aphasia, there is a curious inability to protrude the tongue: this is absent in disease of the right hemisphere. Bilateral glossoplegia commonly results from disease of the nucleus or its neighbourhood, rarely

from symmetrical disease of the lower part of the motor region of the cortex in what has been termed 'pseudo-bulbar paralysis.' Unilateral paralysis, when isolated, is generally due to disease of the fibres of the nerve within or outside the medulla.

SYMPTOMS.—In unilateral paralysis, the tongue at rest is in its normal position in the mouth, but its root is higher up on the paralysed than on the normal side, in consequence of the loss of the tonic, or voluntary, contraction of the posterior fibres of the hyo-glossus. Within the mouth, the tongue is moved freely to the healthy side, but is not moved to the paralysed side. When protruded, it deviates towards the paralysed side, because the protrusion is the result of the action of the fibres of the genio-glossus, and the tongue is pushed over towards the weaker side. In bilateral paralysis the tongue lies in the mouth behind the teeth, and cannot be protruded. If the loss of power is complete, the tongue cannot be projected over the lower teeth. It is broad and flabby, if there is no atrophy, and sometimes when atrophy is associated with fatty overgrowth. When there is wasting, as is generally the case when the nerve or nucleus is diseased, the tongue is shrunken and its surface is wrinkled, on one side or both. The faradic irritability of the muscular fibres is then lost. In unilateral paralysis, articulation and deglutition are little impaired. The pronunciation of labials and the production of falsetto notes may, however, be difficult. In bilateral paralysis, articulation is much impaired. Phonation, however, is perfect, unless the larynx is also paralysed. Mastication is interfered with, because the food cannot be moved about in the mouth. Deglutition is also impaired, because the food cannot be rolled into the fauces; and soft foods, when they reach the pharynx, may be driven again into the mouth, in consequence of the absence of the natural supporting movement of the tongue. Taste is not primarily affected, but may be somewhat dulled, because the patient is unable to move sapid substances over the surface of the tongue.

DIAGNOSIS.—The position of the lesion is indicated by the associations of the paralysis. If the disease is in the motor tract above the nucleus (pons, crus, or hemisphere), there is hemiplegic weakness, partial or complete, on the side of the paralysis of the tongue. In disease of the nucleus the paralysis is commonly bilateral, is associated with paralysis of the lips and throat, and there is usually wasting. Disease of the fibres of origin within the medulla from a small area of softening may be associated with paralysis of the opposite limbs, so that the tongue deviates from the paralysed side instead of towards it. When the disease is at the surface of the medulla, the paralysis is commonly associated with that of the corresponding half of the palate and vocal cord, from disease of the adjacent spinal accessory nerve. In all these cases there is commonly wasting, but it may be slight. The diagnosis of the pathological cause of the paralysis rests on the course of the affection, and on the presence of any causal and associated condition. The chief sources of error in diagnosis arise from the fact that in hysteria the tongue is often voluntarily but persistently protruded towards one side; the nature of the deviation is recognised by its extreme degree and by the freedom of movement within the mouth. In facial paralysis, with lateral deviation of the orifice of the mouth, the tongue may be protruded, consensually, in the middle of

this, and therefore to one side of the middle line of the face, and thus may seem to deviate. A knowledge of the fact will prevent error.

PROGNOSIS.—This is usually unfavourable, on account of the gravity of the disease which damages the nerve or centre. Even in syphilitic cases, recovery is often incomplete unless early and energetic treatment can be adopted.

TREATMENT.—The treatment of paralysis of the hypoglossal nerve is that of the causal disease. Tonics, counter-irritation, iodide of potassium and mercury, with the application of electricity to the tongue if there is reason to anticipate recovery of some nerve-fibres, are the most important remedies to be employed, according to the aetiological indication. The most convenient method of applying electricity is by means of a tongue-depressor in a wooden handle, the blade being insulated by a coating of sealing-wax where it comes in contact with the lips.

2. **Spasm.**—Spasm in the parts supplied by the hypoglossal nerve is rare. The tongue participates in the convulsive movements in epilepsy, is jerked between the champing jaws, and thus becomes bitten. It is sometimes the seat of persistent tonic spasm in hysteria. Cases have been met with in which the tongue is affected with a 'functional spasm' in speaking, analogous to 'writer's cramp,' but these are so rare as scarcely to need detailed description.

W. R. GOWERS.

HYPOSPADIAS (*ὑπό*, under; and *σπᾶω*, I draw, or tear).—A malformation of the penis in which the orifice of the urethra is underneath or behind the glans. See PENIS, Diseases of.

HYPOSTASIS (*ὑπό*, under; and *στάσις*, standing, settlement).—This term is applied to that condition of the veins of a part which consists in an overfulness, with a diminution in the rate of flow of the contained fluid, caused by a failure in the propelling forces of the circulation.

HYPOTONUS.—See NERVOUS SYSTEM, Examination of.

HYSTERIA (*ὑστέρα*, the womb).—**SYNON.** : Fr. *Hystérie*; Ger. *Hysterie*.

INTRODUCTION.—'Hysteria' is a term the etymology of which is misleading, and had best, therefore, be disregarded. It is often improperly applied to cases of simple malingering, and others which do not admit of ready explanation. Its use is best restricted to a condition of the nervous system fairly defined, but the intimate pathology of which is not known, characterised by the occurrence of convulsive seizures, and by departures from normal function of various organs, leading to very numerous and often perplexing symptoms. These are apt to simulate those commonly arising from definite alterations of structure, but differ from the latter in the fact that they may often, even when at their worst, be removed instantaneously, usually under the influence of strong emotion. It would seem that there is a disturbed or congenitally defective condition of the cerebral substance, involving in all cases the highest nervous centres, and in various examples extending more or less also to some of those which preside over automatic phenomena. Partial or complete suspension of inhibitory influence would appear to be the most patent result of the condition, whatever it be; and this is re-

cognised as well in regard to the mental as to the more evidently physical processes belonging to cerebral function. A laugh which cannot be checked, but continues until tears flow or the limbs become convulsed, is a typical example of such a suspension of control, and, if studied, throws light upon the nature of a considerable portion of the phenomena of hysteria. The jerking expirations of laughter arise from excitation of the respiratory centre; and when this excitation, uncontrolled by higher centres, acquires an abnormal strength, it extends to other parts of the medulla oblongata and spinal cord, and produces general convulsions. It overflows, as it were, into other nervous centres, which in health would receive none of the exciting impulse. Between the lowest (automatic) functions of the cerebro-spinal nervous system and the highest (psychical) there is an ever-increasingly complex system of excito-motor processes, which may be in part or wholly under the pathological influence, whatever it be. Hence the *bizarre* character of the hysterical phenomena, and the circumstance that the symptoms always include modifications of those processes which underlie the mental faculties. The suspension of the power of control possessed by the higher centres explains the irregular movements, spasms, and convulsions. In hysteria, hyperæsthesia and pain would appear to be dependent upon such a molecular change being initiated in the sensory ganglionic centres as is ordinarily propagated from the periphery. Hysterical paralysis, on the other hand, signifies that the power of the higher centres in liberating movements is in abeyance. In hysterical anaesthesia it is probably feeling or sensory perception, and not the function of the more immediate sensory apparatus, which is in abeyance, while the reflex actions which result from excitation of sensory nerves may be performed in an orderly manner. A patient may work a needle with fingers which can be touched or pricked without the act being felt. Tactile impressions are conveyed to the ganglionic centres by the afferent nerves, and excite the action of efferent nerves so that the muscles are contracted. What is wanting is the participation of those higher centres in which consciousness runs parallel to this physiological action.

ÆTIOLOGY.—*Predisposing causes.*—It is probable that a state of more or less imperfect development of the higher nervous centres, of congenital origin, very frequently, if not always, underlies the various circumstances which apparently conduce to the hysterical condition.

The female sex is much more prone than the male to the affection, which usually occurs between the ages of fifteen and thirty, and most frequently of all between fifteen and twenty. Luxury; ill-directed education, and unhappy surroundings; celibacy where not of choice, but enforced by circumstances; unfortunate marriages; alcoholism; premature cessation of ovulation; and long-continued trouble—all predispose to hysteria. A somewhat frequent antecedent is a long and wearisome nursing of a sick relation, with much broken rest. The disorder is only exceptionally found in women suffering from diseases of the genital organs, and its relation to uterine and ovarian disturbance is probably neither more nor less than that which obtains in other neuroses. Exception must be made in the case of prostitutes affected with venereal disorders, who are very prone to hysteria. In this class, however, the condition is complicated by the physical and moral

influences to which their life subjects them, and among these alcohol frequently occupies a very important place. Like epilepsy, megrim, and some forms of insanity, hysteria is prone to be intensified at the catamenial period.

The occurrence of hysteria (although comparatively rarely) in males is sufficient of itself to disprove the uterine theory of causation.

Determining causes.—These include painful impressions; long fasting; strong emotions; imitation; and shock to the nervous system, physical or moral.

SYMPTOMS AND DIAGNOSIS.—In the limited space in which it is necessary that the subject of hysteria should be treated, it will be best to describe together some of the most frequent forms which the neurosis takes, and the principles upon which a diagnosis can be made. Hysteria produces symptoms which may be referred to every function of the body. For consideration they may be roughly classed in the following groups, it being understood that all may occur either coincidentally or in succession: (1) *Mental*; (2) *Sensory*; (3) *Motor*; (4) *Circulatory*; and (5) *Visceral*.

1. *Mental*.—The intelligence may be apparently of good quality, the patient evincing sometimes remarkable quickness of apprehension; but, carefully tested, it is found to be wanting in the essentials of the highest class of mental power. The memory may be good, but judgment is weak, and the ability to concentrate the attention for any length of time upon a subject is absent. So also regard for accuracy, and the energy necessary to ensure it in any work that is undertaken, are deficient. The emotions are excited with undue readiness, and when aroused are incapable of control. Tears are occasioned not only by pathetic ideas but by ridiculous subjects, and peals of laughter may incongruously greet some tragic announcement. Or the converse may take place: the ordinary signs of emotion may be absent, and replaced by an attack of syncope, convulsion, pain, or paralysis. Perhaps more constant than other phenomena in hysteria is a pronounced desire for the sympathy and interest of others. This is evidently only one of the most characteristic qualities of femininity, uncontrolled by the action of the higher nervous centres, which in a healthy state keep it in subjection. There is very frequently not only a deficient regard for truthfulness, but a proneness to active deception and dishonesty. So common is this, that the various phases of hysteria are often assumed to be simple examples of voluntary simulation, and the title of disease refused to the condition. But it seems more reasonable to refer the symptom to impairment of the highly complex nervous processes which form the physiological side of the moral faculties.

2. *Sensory*.—Pain, hyperæsthesia, and anaesthesia occur with perhaps equal frequency. The diagnosis of the hysterical origin of such alterations of sensibility is effected partly by excluding, so far as is possible, the presence of other causes, and partly by consideration of any accompanying or antecedent peculiarities of manner and conduct. Hysterical *pain*, where it is associated with some evident local change, is found to be greatly in excess of that which would ordinarily accompany the observed cause. Where pain or hyperæsthesia is complained of in situations and of a character which would commonly point to some existing inflammation, it is necessary, by examination of the pulse and tempera-

ture, to exclude such a condition. Hysterical pain is apt to cease suddenly when the attention is diverted, and to be increased by inquiry and sympathy. Some of the most common seats of pain and tenderness are the following:—

(a) The lower part of the side of the chest (usually the left) simulating intercostal neuralgia, but distinguished from it by the tenderness being widespread, superficial, and not confined to certain points. Pressure here will sometimes occasion disturbances of respiration and circulation.

(b) Some of the vertebral spines, usually in the cervical and upper dorsal region. From the error of mistaking this for commencing disease of the vertebræ numbers of young women have been confined to a couch for months and years, and their health permanently damaged. The points of diagnosis are the patient's antecedents: there is often a history of aphonia, or paralysis, or hysterical fits. Or it may happen that, long after the pain has been first complained of, the patient has been seen to take a prodigious amount of exercise *on some one occasion* without complaint. A very much slighter pressure, too, causes pain than is at all usual in vertebral caries. It has to be carefully remembered, however, that a patient affected with vertebral disease may also be hysterical.

(c) Acute pain in a joint, occurring usually some little time after a slight injury and giving rise to suspicion of inflammation, but distinguished from this by the fact that after a few days of great pain the joint does not feel hot to the touch, and is not swollen, and that the thermometer shows no rise of temperature. The pain is more easily excited, too, by touching the skin than by pressing the articulatory surfaces against each other. See **JOINTS, Diseases of**; and **PAIN IN VISCERAL DISEASE**.

It is necessary to remember that in locomotor ataxy there may be exquisite pains (of a shooting character) having their seat in a joint or its neighbourhood, and accompanied by some localised hyperæsthesia of the skin. The disease rarely affects young females, but it may do so, and the condition is then liable to be mistaken for hysteria. See **TABES DORSALIS**.

(d) Tenderness of the mamma or darting pains through its substance, recalling those of scirrhus. The absence of any lump, and the effect of engaging attention, will serve to ensure the distinction.

(e) Pain in the head of very severe character, 'like a nail being driven into the skull' (*clavus*). This is probably neuralgic, and is by no means confined to the hysterical. There is also a more diffused pain, described as of great violence and exceedingly obstinate. This pain is sometimes suggestive of cerebral tumour, from which, however, it may often be distinguished by the fact that the ophthalmoscope shows no optic neuritis, that there is no vomiting, and that localised paralysis is absent. But very great caution is necessary in coming to a conclusion that severe and long-continued pain in the head is hysterical. Errors of diagnosis in this direction are very common indeed. And here it may be well to say that in an accurate knowledge of the characteristics of the disease supposed to be simulated lies the only safety as regards the diagnosis of hysteria. Nor must it be forgotten that persons with serious organic disease are frequently affected also with hysterical symptoms.

(f) Epigastric tenderness. Careful pressure will often show that the tenderness is at the origin of the

recti abdominis muscles, and not in the stomach. But there is sometimes pain in the stomach itself, and this may be associated with disgust for food or depraved appetite.

(g) Tenderness in one or other iliac region, deep pressure upon which will sometimes evolve hysterical symptoms, and also in some cases of hysterical convulsions will check the paroxysm.

Anæsthesia and *analgesia* are apt to be found sometimes on both sides, but much more frequently in one half of the patient's body, parted off from the other by the median line, and thus involving apparently half the head, face, and trunk, as well as the upper and lower extremities, though it may be in different degrees of intensity. It not seldom happens that the patient is herself unaware of the existence of this insensibility until examination has disclosed it. The loss of sensibility sometimes affects also the special senses; and smell, taste, hearing, sight, and the perception of colour, may each or all be lost on one side. It is frequently associated with tenderness in the iliac region of the same side; or it may be limited to a small patch. The sense of touch often remains while painful impressions and those of temperature cannot be perceived. The *anæsthesia* may be confined to the surface, or involve as well the deeper structures, into which pins may be stuck without evoking signs of pain. Accompanying the *analgesia* it is often seen that the pin-prick employed to test the condition fails to draw blood on the affected side, while readily doing so in the opposite limb. The left conjunctiva is often the seat of *anæsthesia*, so that it may be touched or even rubbed without any reflex movements of the eyelids being excited. So also the pharynx may be tickled without exciting the ordinary spasmodic contraction, and the epiglottis touched by the finger without inconvenience. A very frequent symptom is loss of reflex contraction when the sole of the foot is tickled with a feather or pointed instrument. This is sometimes complete; in other cases prolonged titillation will evoke a plantar reflex of greater or less extent. Where this absence of (or extremely lowered) plantar reflex occurs in a person who has previously been highly susceptible to tickling of the foot-sole, and common sensation is still preserved, it is a very important symptom of hysteria. Such affections of cutaneous sensibility or of reflex action may have to be looked for, as they are often unsuspected by the patient herself. As regards diagnosis, the existence of peripheral nerve-lesions may be excluded by the absence of trophic disturbance or change in the electrical reaction of the muscles. The condition is not likely to be confounded with hemiplegia, unless perhaps when it has immediately followed a convulsive attack, and is accompanied by apparent loss of power in the limbs. Examination of the patient and her history will suffice for the diagnosis.

The other special senses also may be disordered in hysteria. There may be intolerance of light, subjective sense of taste or smell, roaring noises in the ears; or, conversely, loss of sight (either in half of both eyes, or in one eye), loss of smell, or taste, or hearing. Or there may be feelings as of a limb or other part being enormously enlarged, of the body being confined in a stiff case, of the feet being drawn up by strings under them, of 'pins and needles' around the waist, or of numbness and coldness in one half of the body (commonly the left). It may be said generally of the disorders of sensa-

tion that they are capricious in their appearance, coming and going as they would not did they depend upon organic disease (this recurrence is especially significant); that they are very apt to ensue upon some moral shock or convulsive seizure; and that careful examination will prove them to be unaccompanied by such other symptoms as would be likely to be present did they depend upon the organic alteration which they simulate.

3. *Motor*.—The principal motor symptoms in hysteria are local spasm, more or less general convulsion, and paralysis. A common symptom of hysteria is the *globus hystericus*. A lump like an egg appears to the patient to arise from the epigastrium, and, travelling upwards to the throat, causes a sensation of choking, and is often accompanied by an outburst of tears.

Spasm affecting some of the various muscles concerned in the respiratory acts gives rise to a great variety of symptoms highly characteristic of hysteria. There may be cough of a peculiarly sharp, ringing character, constant except during sleep, unaccompanied by expectoration, strongly influenced by moral causes. A little observation will show that the cough does not occur when the patient is quite alone and apparently no one within earshot; but, on the other hand, is greatly intensified by inquiry and solicitude. It ceases during sleep. Auscultation of the chest shows no departure from the normal state. Sometimes, instead of cough, a loud expiratory sound is produced, of most discordant character, resembling, perhaps, a railway whistle, the quacking of a duck, or the barking of a dog; and this may take place irregularly, or may be marked by a curiously distinct periodicity. Or there may be rapid, deep whooping inspirations, with signs of suffocation. Occasionally with the hysterical cough there is a hypersecretion of mucus; and if, as often happens, there is also disturbance of digestive functions and consequent tendency to emaciation, and at the same time such constriction of the air-passages as gives rise to sibilant râles, a *primâ facie* resemblance to phthisis is presented, which can only be distinguished by prolonged observation, aided by the stethoscope and thermometer. Laughing and crying are very frequent forms of expiratory spasm. Yawning, hiccough, and sneezing are also met with. *Clonic spasm* of muscles, especially of those moving the head and shoulders, or back, is not uncommon; or one of the muscles of the thigh may be so affected, and the apparent pulsation caused by the rhythmical contractions give rise to a suspicion of aneurysm.

Tonic spasm of one or more muscles of a limb is still more frequent. It is often very obstinate, and after enduring for months or years may suddenly resolve without any permanent alteration being left behind.

Contracture of a limb thus produced may continue during sleep, and even resist the influence of chloroform inhalation, unless this is pushed to its full extent. Should one of the abdominal muscles be thus affected, an abdominal tumour is produced, which may be mistaken for some growth in the cavity; and if the pulsations of the aorta should be communicated to it, a strong *primâ facie* resemblance to abdominal aneurysm is caused. The best mode of diagnosis is by faradisation, which, if persevered in for several minutes, will exhaust the muscular contractility and cure the ailment if it be of this kind. If it is not a 'phantom tumour' of this

description, but a genuine growth, the muscle will be contracted by the current, and it may then be possible to feel the tumour as something evidently distinct from the muscle.

Convulsive seizures are of common occurrence, and are usually preceded by a sense of suffocation, difficulty of swallowing, pain in the belly or stomach, headache, vertigo, or some indescribable sensation in one of the extremities. There is often a cry as of one being choked, unlike the peculiar wailing shriek which may usher in the epileptic seizure. Usually there is not the extreme suddenness of attack which characterises epilepsy, but the patient may be manifestly struggling against the seizure for a small but appreciable interval. When at last she falls, she does not usually do so with violence enough to receive severe injury, and positions of danger are generally avoided. The epileptic not infrequently falls into the fire, the hysterical patient never. The spasms of muscles which succeed are often tetanic in character, and sometimes wear an aspect of design—the patient grips articles with her hands or teeth. The face may be more or less red. In epilepsy it is usually first pale and then livid.

There is often more or less complete opisthotonos, which is usually absent in epilepsy. It has been doubted whether consciousness is ever completely lost in an hysterical fit; but though for the most part perhaps it is retained during the attack, there are certainly cases in which it is to a great extent in abeyance. It is characteristic of hysteria that, however rapid and violent the contortions, the patient usually avoids inflicting any serious injury upon herself. During the attack gesticulations and language are apt to be used which may be reproachful, or marked by an amatory character as regards some bystander, such as is calculated to cause him considerable embarrassment. There may be a single convulsive seizure, terminated by a fit of weeping and the passage of a large quantity of almost colourless urine of low specific gravity. Or there may be a succession of attacks extending sometimes over several hours. The tongue is not bitten. As a rule, the hysterical patient rapidly returns to her ordinary condition after the outburst is completed, and fails to show the heaviness and tendency to deep sleep which is characteristic of epilepsy. Where there is during many hours a long-continued succession of fits with brief intervals of immunity, considerable doubt may arise as to the nature of the attacks, because a very similar, numerous, and rapid recurrence of fits sometimes takes place in true epilepsy. We are indebted to Charcot for the observation that while in the case of the epileptic seizures of this kind the temperature is observed to rise greatly (attaining, for instance, a height of 105° F.), no such great increase is noted when the fits are of hysterical origin—a slight elevation only occurring. The variety seen in the character of hysterical convulsions suggests that the pathological influence involves the nervous centres, sometimes more and sometimes less extensively; giving rise to various kinds and degrees of muscular movements, from those of a highly co-ordinated or quasi-voluntary kind, down to those of a simply tetanic form. These latter would appear to indicate either that control of the reflex function of the spinal cord is temporarily suspended, or that the cerebellar influence, as Hughlings Jackson suggests, is being allowed to have full play, owing to some peculiar condition of the cerebrum interfering for a time with its normal

power of antagonism. But it must be borne in mind that the hysterical patient may, like others, become epileptic, and that there is nothing on the other hand to prevent the chronic epileptic from betraying symptoms of hysteria. Indeed this is not at all infrequent in the female epileptic. Such mixed cases are often difficult of diagnosis, and it is usually only a prolonged observation which succeeds in distinguishing the nature of the condition. Movements which somewhat resemble those of chorea are occasionally met with, but their character and the surrounding circumstances usually make it easy to distinguish them.

Paralysis may affect any of the limbs in hysteria, but paraplegia is the more usual form. Hemiplegia is comparatively rare. The muscles retain their nutrition. Where the condition has existed for a considerable period there is often at first a slight loss of irritability to induced currents, but after a very few applications this becomes normal. At first, too, considerable electro-cutaneous and electro-muscular insensibility may be present. If the form of paralysis be hemiplegic, the face is not affected; if paraplegic, the sphincters are not paralysed, and although an apparent incontinence of urine sometimes occurs, there is no cystitis, and the urine does not become ammoniacal. There is never any bed-sore. If the arm be the limb affected, and the examiner, after flexing it slightly at the elbow-joint, leaves go, it will sometimes remain in the flexed position, which it would not do in a flaccid organic hemiplegia. It is noteworthy that, in half the cases of hysterical paralysis, there is no history of antecedent convulsions. Cutaneous anaesthesia of the extremities will give rise sometimes to a pseudo-paralysis, and muscular anaesthesia may cause symptoms of an ataxic character. These may be distinguished from the result of organic change by careful examination. Hysterical speechlessness may be distinguished from aphasia by the patient being able to write down with great facility the wishes she is unable to express in speech; and from localised paralysis of the tongue, by her being perfectly able to protrude the organ and to swallow.

4. *Circulatory*.—There may be syncope which will simulate dying. After an indescribable sensation at the heart—a fulness, or stifling feeling—the pulse becomes almost imperceptible, the patient is speechless, and, for periods varying in length, is apparently in a most precarious condition, recovery taking place after prolonged sighing. Or there may be tumultuous action of the heart. The abdominal aorta (and sometimes also other arteries) is occasionally the seat of powerful pulsations, which are visible in their effects upon the abdominal wall and strongly suggest the existence of aneurysm. The capillary circulation may be deranged in the two directions of hyperæmia and ischæmia. In the former there is a patch of redness of the skin, accompanied by a feeling of burning and tenderness; in the latter, which is especially seen in conjunction with analgesia, the skin is pale and no bleeding follows the pricks of a pin. In a recorded case, pressure upon a tender spinous process checked the radial pulse for a time.

5. *Visceral*.—Vomiting is sometimes a very obstinate symptom, all food taken being speedily ejected, the condition lasting a surprisingly long time, often for many months, sometimes for years, usually without so much prostration as might be expected, but nevertheless with great loss of weight.

Or there may be such an active aversion from food as renders it very difficult to support nutrition; or a depraved appetite may cause substances to be swallowed which have no nutritious property. In the belly there is frequently a hyper-secretion of gas with spasm of the bowels, causing borborygmi and noisy eructations. Intestinal gas may be imprisoned between two points of spasmodic contraction of the intestine, giving origin to a tumour capable of being moved about in the abdominal cavity, and of sudden resolution. These 'balloons,' as they have been called, are probably sometimes mistaken for tumours of the spleen, kidney, or other organ. It is not uncommon to have retention of urine, the bladder becoming greatly distended, but contracting at once and expelling its contents if the patient be placed in a hip-bath, and a bucket of cold water thrown over the pelvis. In other cases there is an unduly frequent desire to empty the bladder, and there may be some apparent incontinence. The secretion of urine may be suppressed almost entirely (but this is very rare), the little urine that is passed containing an unusual proportion of urea, which is also found in the vomiting accompanying this condition.

There is sometimes very obstinate constipation, extending over weeks or even months, and giving rise to enormous impaction of fæces—occasionally also there is diarrhoea.

Cases occur in which symptoms of cerebro-spinal sclerosis of the insular or disseminated form, especially paresis of one or other limb in turn, after persisting perhaps for many months in a young woman, rapidly or even suddenly disappear. This circumstance is often supposed to show that the case was one of hysteria. It is probable, however, that the view still generally held that a shifting of loss of power from one limb to another is really characteristic of hysteria is quite an error. The hysterical woman who has lost all power in her legs will, it is true, very often later on (while still paraplegic) lose the power of one arm (usually the left), but in the writer's experience she is not prone to lose the power in a limb, then recover it, and then lose it in another. The idea of this shifting of powerlessness being strongly suggestive of hysteria has probably arisen from the mistakes in diagnosing as hysteria cases of insular sclerosis, which must have been continually occurring before the latter disease had been differentiated. So in regard to vision. The hysterical patient will become quite blind of one eye, while the patient affected with insular sclerosis will only describe obscurity of vision in one eye which *gradually* becomes more pronounced. It is doubtful if the sight is ever entirely lost. The writer cannot call to mind, since he has been better acquainted with insular sclerosis, any case of simple hysteria in which first one eye lost some amount of vision for a time, and recovered, and afterwards the other eye behaved in a similar fashion. This is not at all uncommon (is indeed frequently the case) in the course of insular sclerosis. The marked and almost constant occurrence of hysterical symptoms in the earlier stages of insular sclerosis often tends to obscure the diagnosis, and a very guarded prognosis becomes necessary. It has been common to class such cases with those of hysterical paralysis; but it is probable that they are examples of insular sclerosis recovering only for a time, as is characteristic of the disease. Many cases of insular cerebro-spinal sclerosis are still erroneously diagnosed as hysteria. See MULTIPLE SCLEROSIS.

SEQUELÆ.—Hysterical symptoms sometimes pass into those of mania, melancholia, and occasionally also of dementia.

PROGNOSIS.—This is favourable as regards life, death from hysteria being very rare. Recovery for a time is common enough, but too often there is a return of the disease, the symptoms being usually of a different kind. Some patients will run through almost every conceivable phase of the disorder in turn. As a rule there is a tendency to cessation of the disease after the climacteric period. It occasionally happens, however, that the disease is continued into an advanced period of life.

TREATMENT.—If Medicine were in a position to regulate the mode of life, food, education, and especially the selection for propagation of the species, it is probable that in succeeding generations hysteria would become more and more rare in the race. In many cases it can do but little for the individual. Intercurrent maladies must of course receive the treatment proper to them. Where anæmia is present, much good may often be done by iron and arsenic. States of malnutrition tend to precipitate and intensify hysterical symptoms; and to remedy these is often to do much for the concomitant nervous disorder.

But probably the greatest amount of benefit which can be brought to bear upon the hysterical patient is through her surroundings. A girl who has not spoken above a whisper for months while at home, will often recover her natural tone of voice in a week if placed under the judicious discipline of strangers. This is a well-known circumstance, and the fact has tended very much to the belief that hysteria is simply vicious simulation. Such an inference is unjust.

That an altered relation of the ganglionic nerve-cells to the blood-supply forms at least a part of the pathology of hysteria appears probable from the effects of fasting in provoking hysterical outbursts, and the influence of food and stimulants in postponing them. Ammonia inhaled by the nostrils is a well-known and valuable agent for the purpose. Alcohol should be avoided altogether, as there is great danger of excess.

It is through the sensory nerves that the most rapid influence is brought to bear upon the hysterical condition. Thus cutaneous anesthesia and hyperæsthesia may often be rapidly cured by the application of strong induced currents to the affected portion of skin; aphonia by acting in a similar way upon the skin covering the larynx. Paralysis of the limbs is in many cases quickly cured by the same means.

Hysterical convulsions may almost always be cut short by douching the patient very freely indeed with cold water. This should be poured from a height upon the face. For a few seconds there is no perceptible effect, then the breathing becomes gasping, and the patient seeks by moving away to avoid any further application. It often happens that the remembrance of this treatment serves to prevent a repetition of convulsions, but it would be wrong to conclude from this that the proceedings of the patient had been voluntary. The effect of the cold douche is to create, through the medium of the cutaneous nerves, a sudden change in the character of the blood-circulation, which may well influence the state of the ganglionic nerve-centres. The supposition seems fair that to remember the shock is to have a weak excitement of the nerve-

centres which were strongly excited by the application.

Bromide of potassium, which is of such value in the *grand mal* of epilepsy, has no influence in preventing hysterical convulsions. In a doubtful case the exhibition of this drug is therefore useful for purposes of diagnosis. Valerian (the powder or tincture) has an unquestionable effect in the convulsive and spasmodic symptoms of hysteria, little or none probably upon the paralytic phases. Asafetida by enema is useful in tympanites and colic of hysterical origin. Small doses of strychnine and opium are useful in relieving some of the distressing feelings complained of by hysterical patients.

Dr. Weir Mitchell, of Philadelphia, has introduced a mode of systematic treatment of hysteria and nerve-prostration, which has lent important aid to our means of dealing with cases of this kind. The treatment essentially consists in the complete isolation of the patient, who lies in bed and is fed and attended by an intelligent nurse. Under the influence of massage of the muscles of the trunk and extremities, conducted twice a day for an hour or more, the patient becomes able to take large quantities of milk (from 60 to 100 oz. in twenty-four hours), besides three full meals of highly nutritious food. By these means the nutrition of the body undergoes a remarkable improvement, one or two stone of weight being often added; the muscles become firm, the skin soft and elastic; the complexion assumes the hue of health; the patient regains natural sleep if this has been lost; while various morbid symptoms—pains, local tenderness, contracture, loss of power in the limbs—disappear. It is especially in cases where signs of emaciation have been present that this mode of treatment may achieve extraordinary success.

It is often a question whether the hysterical should marry. Where the disorder is slight and the general health is good, marriage may be advised, supposing that the prospects of a happy union are favourable. But in very severe cases, and especially when there is also a strong neurotic history in the family, it should be discountenanced. Nothing but harm can be expected from the strain of domestic cares upon a congenitally defective nervous system.

T. BUZZARD.

HYSTERIA, TOXIC.—See LEAD, Poisoning by.

HYSTERICAL INSANITY.—Almost every variety of insanity may present in certain patients features which are commonly known and termed 'hysterical.' Melancholic individuals will be afflicted with hysterical paraplegia or other paralyses. Some will become cataleptic or apparently unconscious. Others will display all the phenomena of hystero-epilepsy. Not infrequently do we see a violent outburst of acute mania culminating and subsiding in a brief period of time, resembling in this an ordinary attack of 'hysterics.' It may be doubtful, however, whether hysterical insanity should be looked upon as a special variety of the malady. It seems more correct to look upon it as insanity occurring in hysterical patients, and characterised by the phenomena peculiar to them. We may expect sudden changes of symptoms, sudden improvements, and sudden relapses.

PROGNOSIS.—The prognosis is unfavourable, as this form of insanity is found in patients of an unstable nervous organisation, prone to frequent derangement. Even if recovery takes place, attacks are not unlikely to occur subsequently.

TREATMENT.—Such persons above all others require moral treatment. Medical treatment should be directed towards the improvement of the general health rather than the removal of special symptoms.

G. F. BLANDFORD.

HYSTERO-EPILEPSY.—SYNON.: Fr. *Hystéro-épilepsie*; *Hystérie Epileptiforme*; *La Grande Hystérie*; Ger. *Hystero-epilepsie*.

DEFINITION.—This term has been so loosely applied that it is incapable of strict definition. It is to the French school, and especially to the late Professor Charcot of Paris, that we owe its application to cases of the convulsive form of hysteria displaying an amount of severity such as is rarely witnessed in this country. The term is sometimes allowed to cover any or all of the more marked symptoms of hysteria, whether sensory, motor, or visceral. In England its etymology has led to its being applied to a class of cases, essentially epileptic in origin, but characterised by convulsions and other motor phenomena of a 'purposive' aspect. Under these circumstances it is only necessary to refer to the articles on EPILEPSY and HYSTERIA for further information.

ICE, Therapeutic use of.—See COLD, Therapeutic use of.

ICHTHYOSIS (ἰχθῦς, a fish-scale).—SYNON.: Fish-skin Disease; Fr. *Ichthyose*; Ger. *Fischschuppenausschlag*.

DEFINITION.—A disease which has obtained its name from the division of the cuticle into polygonal plates somewhat like the scales of the fish, although no overlapping exists. The skin is dry, rigid, rough, and greyish-green, often of the hue of the upper surface of the turbot; and the cuticle exfoliates, in some places as dust, in others as thin shining laminæ like mica or bran.

ÆTIOLOGY.—Ichthyosis may be regarded as a defective development of the skin, usually, however, appearing some months after birth. In rare instances it has arisen in adults. Males are affected twenty times as often as females. Heredity sometimes obtains. The degree of its manifestation may depend on various circumstances, especially those relating to scanty food and want of cleanliness. It may be regarded as endemic in the Molucca Islands.

ANATOMICAL CHARACTERS.—The cuticle is abnormally copious; the fibrous tissue of the derma is condensed; the papillæ are enlarged and lengthened, and are sometimes apt to bleed on

slight injury; the areolar layer is lax and fatless, and the whole integument wants succulence and elasticity. Further, the cuticle is hard and brittle,—the inorganic matter, mainly phosphates and silica, being increased fourfold—and cracks along the lines of motion or wrinkles of the skin. The fragments are powdery upon the neck, the front of the trunk, and the flexures of the joints, angular and prominent on their extensor aspects, and smooth and polyhedral on the rest of the limbs. The follicles are filled with dry epithelium and sebum, which in places may concrete and add to the thickness of the crust. The skin as a whole forms coarse wrinkles, and, from the laxness of the subcutaneous areolar tissue, moves freely over the fascia. The oily, and sometimes the aqueous, secretions are scanty; an unpleasant odour is often exhaled; and the transparency and lustre of the healthy skin are wanting. The hair is coarse and brittle. The health of the patient is usually good, but cardiac hypertrophy and asthma have been noted. The cold of winter is felt severely, and death often results from pulmonary complaints.

MODIFICATIONS.—Ichthyosis varies according to site. On the limbs it is most symmetrical, and the scales are largest; on the hands and feet the cuticle is horny, and there are deep wrinkles; and on the face the detached edges of the plates cause great roughness, and the complexion is altered to a brick-red. Varieties are also produced by the amount of sebum, which may form either thick scales or projecting spines. Such modified forms have suggested several synonyms. Thus, when dryness of the skin is conspicuous it has been termed *xerodermia*—but this may progress to a more severe form. When the network of lines bounding the scales is regular and widely stretched, from the tightness of the whole integument, the name 'harlequin skin' has been applied, such instances being usually congenital and the birth premature. When the smooth surface has a mother-of-pearl polish it has been called *ichthyosis naecea*. When the concreted epidermic and sebaceous substances resemble the scales of reptiles, the term *ichthyosis serpentina* is applied, although the monitor is the reptile whose skin it is most like; and finally, the variety in which long spines appear is designated *ichthyosis hystrix*, the 'porcupine disease.' Malformations of the eyelids, ears, and fingers have been frequently found in ichthyotic subjects. The disease has been known to disappear after eruptive fevers, and after mercurial salivation. Palmar and plantar keratosis is closely allied, but it has no relation to Darier's disease, which has been proved to be microbic. See p. 362.

TREATMENT.—The principles of treatment are as follows: First, we must promote an improved nutrition of the body by the use of a generous diet, including fresh fruits, and excluding oatmeal and wholemeal. Cod-liver oil, arsenic, iron, or other tonics are indicated. Secondly, it is necessary to remove the excess of epidermic matter and sordes, which is best effected, when the disease is limited, by resorcin or salicylic acid; the mixture of salicylic acid, tincture of Indian hemp, and flexible collodion sold as 'corn-solvent' is useful. When the disease is extensive, ablutions with soft water and soft soap, and especially the Turkish bath and shampooing, are beneficial. Thirdly, we have to stimulate the circulation and innervation of the skin by friction and inunction with such substances as lanoline, cod-liver oil, or cacao-butter mixed with

glycerine. The salve-mulls and super-fatted soaps, as used by Unna, give great relief in localised cases. Injection of pilocarpine has been used to increase sweating and thus soften the cuticle.

E. D. MAPOTHER.

ICTERUS (*ικτῆρ*, a weasel; with yellow eyes). A synonym for jaundice. See JAUNDICE.

ICTUS SOLIS (*ictus*, a stroke; *sol*, the sun). A synonym for sunstroke. See SUNSTROKE.

IDAHO HOT SPRINGS, in Clear Creek County, Colorado, U.S.A.—Thermal waters. See MINERAL WATERS.

IDIOCY (*ιδιώτης*, a private individual, a person holding no public position; hence a layman or unskilled person, an ignorant clumsy fellow).—**SYNON.**: Imbecility, Feeble-mindedness; **Fr.** *Idiotie, Idiotisme, Démence innée*; **Ger.** *Blödsinn, Idiotie, Idiotismus, Narrheit*.

DEFINITION.—Mental deficiency occurring during infancy and the early periods of life and dependent upon imperfect development of the brain, whether due to transmitted qualities, injury, malnutrition, or disease.

NOMENCLATURE.—Popular usage associates the name 'idiot' with the pronounced and more degraded types, while the term 'imbecile' has come to be used of those cases above the lowest grade, and 'feeble-minded' of a higher level still, though each of these terms has been and is still used by some, and especially by American writers, of the whole group. Legally, idiot and imbecile are used as synonymous terms in the Idiots Act 1886, as opposed to lunatic, though they are included under the term 'lunatic' in the Lunacy Act 1890.

The term 'feeble-minded' does not appear on the Statute Book, but the Elementary Education (Defective and Epileptic Children) Act 1899 provides for children who, not being imbecile and not being merely dull or backward, are defective, that is to say, children who, by reason of mental or physical defect, are incapable of receiving proper benefit from the instruction in the ordinary public elementary schools, but not in special classes or schools for such children. The mentally dull and backward children owe their condition to a vicious environment after birth in respect to nutrition (short of disease), home care, and education, and do not come under our definition.

DESCRIPTION.—It may be premised that we have to deal with a great variety of cases traceable to many causes, one outcome of which has been that the centres in the brain which form the substratum of mind have suffered during their development. Hence arises a defect in mental capacity, ranging in extent from a slight departure from the normal to that condition of profound *amentia*, in which only the organic functions persist and the unfortunate subject perceives nothing, knows nothing, does nothing.

The cardinal symptom is the mental condition; as a rule the whole range of conscious states is impaired, but in some cases the intellectual power, in others the moral sense, is more particularly affected. Owing, however, to the intimate relation of the nerve-centres to each other and the close dependence of the body on the nervous system, both as regards function and nutrition, we find that the mental defect is commonly accompanied by profound physical

alterations. As it is impossible to construct a type that shall satisfactorily represent such varied conditions, the following statement of the more striking abnormalities found in different cases, either singly or combined, will serve for a general description.

The height and weight of mentally defective children are less than normal, but the difference is less on the average in girls than in boys. The skin is often coarse, deficient in elasticity and tone, and shows thickening of the subcutaneous tissue. In some cases it is dry and branny, in others very greasy from excessive secretion of sebum; in others, again, perspiration is excessive at the expense of the secretion of urine. Molluscous appendages are very common, and extreme obesity is occasionally seen. A general and striking character is met with in the teeth, which are often incomplete in number, poorly developed, much coated with tartar, and loose, very often crowded and irregular. The eruption of the teeth is much delayed, and the gums frequently call for attention. The muscular system, in addition to the paralyses and contractures due to specific nerve-lesions, commonly shows a general lack of tone due to deficient cerebral activity, though the reverse condition is sometimes seen owing to general loss of control. The record written in the bones is permanent and more explicit, and is often a clue to the period of onset and the nature of the case. They are sometimes very brittle, and the osseous deformities are very striking. Those of the head have naturally attracted most attention. It is now generally agreed that the natural growth of the skull depends upon the healthy development of the brain, and that cerebral conditions are more likely to cause than be caused by the malformations seen in the skull. Among these are heads too small, too large, or asymmetrical; skulls short from back to front, round and high; with overhanging or retreating forehead, or very small in the occipital region. Frequent and significant among the anomalies are strongly marked ridges in the lines of the sutures—especially in the interfrontal, which produces a ‘prow-shaped’ cranium; and in the sagittal when the skull is called ‘scaphocephalic’ from the likeness of the ridge to a boat’s keel; this is specially marked when, as sometimes happens, the head is also flattened on either side of the ridge. A similar ridge is also found over the coronal suture. This condition appears to depend on delayed ossification; while the occasional obliteration of the sutures points to its premature completion. On the other hand the lines of the sutures may be marked by shallow furrows, while the centres of ossification are the site of pronounced bosses. In cases with hydrocephalus the usual cranial conditions are found (see HYDROCEPHALUS). A general enlargement of the cranium, especially in the vertical direction, is associated with hypertrophy of the brain, and the extreme cases of microcephaly, with receding forehead and a circumference of 17 inches or less, usually present a brain cortex of extreme simplicity as regards convolutions, or a porencephalous condition.

Side by side with these cranial anomalies we find malformations of the bones of the face, and more especially of the jaws. These so-called ‘developmental neuroses’ appear to depend upon errors of brain-development occurring early in intra-uterine life. The chief points are general smallness of the face, narrow and high palate, V-shaped or saddle-shaped dental arch, enlarged alveolar processes,

receding lower jaw, orbits very close together or very wide apart, and facial asymmetry.

The circulation is generally feeble, rendering the patient liable to chilblains, and the processes of repair slow. The temperature of the body is commonly subnormal. The digestive system is very liable to be deranged by defective mastication, and great care is necessary in the preparation of the food and in the exclusion of unsuitable articles of diet. Constipation readily occurs from defective innervation, and changes of temperature and errors of diet readily produce diarrhoea. Congenital hernia is common. The respiratory movements are wanting in vigour and are often not under voluntary control; hence the assistance they afford to the circulation is very feeble, and these subjects are very liable to succumb to pulmonary affections; further their low resisting powers render them very prone to contract tuberculosis if placed in unfavourable circumstances, as on clay-soil, or in ill-ventilated rooms. Obstruction to respiration is sometimes caused by nasopharyngeal adenoids, which produce characteristic changes in the face and chest, and by disturbing the cerebral circulation or causing deafness further hamper the intelligence.

The sexual organs are often imperfectly developed, phimosi, undescended testis, and undeveloped ovary being common; puberty is generally delayed. The ears are often defective in their conformation, and their situation abnormal or asymmetrical.

While the presence of one or other of these morphological faults is commonly found, this is not always the case; on the other hand, many of them are met with in mentally normal individuals.

Turning now to the nervous system, we find that examples of disordered function are very common and highly significant. Generally speaking, there is a want of tone and vigour, as seen in the inability to retain the saliva and in the difficulty some patients have in standing. All reactions tend to be slow and movements slovenly, and there is often some inco-ordination with a loss of finer movements. Thus those who are able to write rarely hold the pen in a facile manner; walking is generally acquired late, and there is difficulty in following objects by moving the eyes only. The art of cutting up and conveying food to the mouth is learnt slowly and with difficulty; this is also true of putting on and fastening the clothes, and performing ablutions.

In some patients movement is almost wanting, in others it is continual and sometimes rapid. Prominent among the abnormal movements are those due to epilepsy, and the ataxia, tremor, and athetosis associated with cerebro-spinal degenerations.

In addition to these a number of striking automatic and impulsive movements are met with, such as swaying to and fro, spinning round and round, walking on the toes, twiddling the fingers in front of and near the eyes, grinding the teeth, beating the head and face, and making grimaces and rhythmic noises. These are characteristic of low-grade cases. Right-handedness is far less universal than among normal persons. The name ‘microkinesis’ has been applied to small slow rhythmic movements often seen in fingers. The control of bladder and rectum is often defective, the fault lying, as a rule, with the higher centres in the brain.

Speech is very commonly affected, and is often

absent or nearly so. The most usual defects are a dysarthria and a lack of musical quality and proper pitch, with perhaps a 'sing-song' rhythm. It is far more usual for these conditions to depend upon mal-development of the higher brain-centres representing the speech-organs than upon any malformation of the organs themselves, which, unless very marked, rarely causes trouble in cases where the higher centres are healthy. In some instances the absence of speech probably depends upon a condition of the highest centres which precludes the formation of ideas, and so the need for language; even gestures may then be wanting. Speech is usually acquired very late, and often remains infantile in character or merely automatic or echolalic. At the sudden mental breakdown which marks the onset of some cases speech may be lost completely or nearly so, and when the mental impairment is severe the power of speech is rarely re-acquired. Stuttering and stammering occur in all their usual forms among the higher grades of idiocy, rarely in the lower. The presence or absence of speech cannot be taken as a measure of the intelligence. Its absence is a serious bar to progress; and this is especially the case when the difficulty lies in the central processes by which words are perceived as having meaning. A high degree of intelligence is compatible with simple motor or sensory aphasia. Deaf-mutism is rarely found combined with idiocy, and when so found cannot be dealt with by the oral method of teaching. See DUMBNESS.

Vision is very often impaired by such defects of the eye as hypermetropia, irregular astigmatism, congenital cataract, strabismus, and nystagmus; and visual perception also seems to be blunted in many by reason of central nervous defects. A large proportion are born blind, a few become so in the course of development. The sense of taste is often defective, sometimes perverted so that repulsive things are eaten. Medicines are as a rule readily administered. Smell is in a few cases extremely acute, though usually it is below normal. Hearing, when affected, is generally so from central causes, as seen in cases combined with athetosis, or from naso-pharyngeal obstruction. General tactile sensibility seems to be obtuse, or to be acute in unusual places only, as the head or tongue. This accounts for the tendency to utilise the tips of the fingers much less than the normal child does, and the clumsy manner of holding a pen or a needle. Some delight in gentle stimuli, others in head-beating. Pain is often borne with wonderful callousness or is not felt as pain. Thus one sees analgesia to the knife in opening an abscess or to a burn; in other cases there is hyperæsthesia, or extreme irritability, so that gravel may be rubbed on the skin to give relief till it is quite raw. Even the organic reflexes seem to be sluggish, as shown by the frequent absence of cough in phthisis, and its general ineffectiveness in pulmonary affections. The vaso-motor system also reacts slowly to external changes, rendering the patient liable to take cold readily.

Whatever the accompanying anomalies of structure, nutrition, or sensori-motor reaction, the essential factor is the mental condition as directly expressed in language, habits, instincts, conduct, attention, volition, and the emotions. It is by the meaning rather than the manner of the movements by which the mind expresses itself that any case must be ultimately gauged. Some of these points will now be considered.

Perhaps the best index to the general mental aptitude is the intensity and persistence of the attention, and for educational purposes this forms the most useful basis of classification. Where sense-impressions fail to arouse percepts or even reflexes, attention is extremely low or absent, and instruction is impossible; where perception is present but unaccompanied by intelligent interest and pleasure it is still low, and renders training slow and difficult. A well-developed voluntary attention to either external conditions or existing ideas is hardly ever found. On the other hand, the attention may be preoccupied with organic sensations, or concentrated on a narrow intellectual avenue at the expense of all others. The rousing of a healthy attention by repeated stimuli likely to interest is the basis of training (see CHILDREN, TRAINING OF). It is owing to inefficient attention that spontaneous play is so rarely found; this trait leads the normal child to leave the idiotic severely alone, and the theoretical advantage claimed to be derived from association with ordinary children is generally found in practice to be non-existent or even a negative quantity. Imitation is common in its lower reflex forms, less so as a spontaneous well-directed function. Memory is proportionate to the strength and duration of sense-impressions and the attention to them. Where special interest is aroused and attention developed special memory-aptitudes are acquired, often greatly in excess of the general level of mental capacity. A similar one-sided skill may be acquired for manual work, drawing, music, or calculation, and extreme acuteness of vision has been cultivated by the habit of looking for and picking up every shining particle seen on the floor.

Pleasure is very generally aroused in these cases by music; this does not as a rule indicate any special æsthetic sense; it is sounds and rhythm which attract, even though discordant, jarring, and monotonous. Simple airs are readily learnt and reproduced by many, and sometimes there is exceptional power in this direction. Some defective children take a delight in long and uncommon words and great precision of language, others are extremely loquacious; but as a rule the vocabulary is limited to emotional expressions and the most ordinary requirements of concrete daily life. The practice of speaking of the 'self' in the third instead of the first person is very usual. Excessive eating is common, though some would starve if the food were not placed in their mouths. The sexual instinct is feeble, sometimes wanting, perverted, or exaggerated.

Owing to the rudimentary nature of the ideas of which they are capable, the mentally deficient, with few exceptions, live entirely in the present, have no ambitions, regrets, or anxieties, suffer little pain at the loss of near relatives, and are untroubled by their own condition if they recognise it. They have, as a rule, no true religious sentiment, and their ideas about the unseen world are of the most primitive and crude nature. They are easily led, and tend to lean upon others, and they readily make themselves at home in fresh surroundings. They have few social bonds among themselves. They are, as a rule, frank, docile, affectionate, and timid, but in a few cases sullen, spiteful, deceitful, obstinate, or passionate.

Classification.—In the classification of a symptomatic group such as this, it is difficult to escape a cross-division. Thus classes have been made based

partly on anatomical conditions, partly on the supposed cause, mode of onset, and leading symptom; the whole group has been divided into apathetic and excitable idiots from the point of view of the emotions or temperament, and the powers of attention and speech have been suggested as a basis for grouping the various grades. The most generally useful plan is to take a biological basis for the main divisions and to group the cases under these in accordance with such ætiological and pathological factors as we are able to ascertain. All cases may be regarded as originating either in a transmitted tendency already present in the fertilised ovum or in a defect acquired by it subsequent to fertilisation. The transmitted tendency may be realised or the defect acquired either before the onset of labour when the case is *congenital*, or later when it may be called *developmental*. Of the acquired cases some are *accidental*, that is, due to conditions of an adventitious nature occurring somewhat suddenly; the rest may be described broadly as *nutritional*, that is, dependent on causes of a more intrinsic nature and affecting the nervous functions in a more gradual manner.

For convenience of description, the following types have been distinguished: Microcephalic; Hydrocephalic; Hypertrophic; Paralytic; Epileptic; Eclamptic; Toxic; Traumatic; Post-Febrile or Inflammatory; Syphilitic; Athetotic; Mongolian; Cretinous (*a*) Sporadic, (*b*) Endemic.

The majority of cases are congenital, and as a rule present some of the physical stigmata already described; the developmental minority may manifest an average intelligence through infancy, and even up to puberty, but break down mentally generally during one of the critical developmental epochs, birth, first and second dentition, and puberty. Speech may be lost for a time or permanently, and there is definite retrogression in mental power. They may possess the crested skull, deformed palate, &c. The accidental cases are the fewest in number: these individuals may be quite free from physical defect and brilliant mentally, and then the intellectual functions may be suddenly completely destroyed without hope of recovery, as, for example, by an attack of meningitis or other injury to the brain.

The *Mongolian Type* forms so well-marked and distinct a variety that it deserves special description. The growth is always stunted, the head and face round and small, with a small retreating lower jaw and an absence of prominent features; the skin is dry, coarse, and readily irritated; the hair is sparse and straight, and is liable to alopecia. The ears are small and closely set, the hands short, broad and spade-like, the nails and teeth ill-nourished, the opening for the eyes too small and obliquely set downwards and inwards, giving the almond-eyed appearance. It is further diminished by a fold of skin over the internal canthus, the epicanthic fold. The tongue is long and fissured transversely, and the lips also are fissured. The children tend to adopt the tailor's posture when sitting. Speech is defective, stuttering and indistinct. They are mimics, obstinate and fairly educable, but show widely differing degrees of intelligence. They are often the late-born children in a family or come of phthisical stock, and have been described as 'unfinished children.' They do not respond to thyroid-feeding as cretins do.

Cretinism is myxœdema occurring in early life and

dependent on absence of the thyroid gland. The mental condition is thus secondary. Cretins show great stunting and deformity, marked myxœdematous thickening of the subcutaneous tissue, a pendulous abdomen, supraclavicular tumours, and a muddy complexion. They respond rapidly to thyroid-extract both mentally and physically. Sporadic cretins are very rare as compared with Mongols, and do not amount to one per cent. of all cases.

ÆTIOLOGY.—In the production of idiocy two or more factors may be working together to the same end, either of which alone might have been insufficient. It thus becomes difficult sometimes to determine the principal or even any cause. In few families is the history quite free from suspicion of taint, and so attention may be directed to this where the influence of maternal or other conditions, such as masturbation, is more directly responsible. On the other hand an unstable nervous inheritance may not be recognised and the blame ascribed to a harmless fall.

The following are the most important conditions responsible for mental defect:

A. TRANSMITTED: Phthisis; Insanity (including Feeble-Mindedness); Epilepsy; Neuroses such as Asthma, Deafness, Chorea, Nervousness, &c.; Constitutional Debility.

B. ACQUIRED: (*a*) *Nutritional*.—Maternal Ill-health, e.g. Vomiting, Uterine Hæmorrhage, &c.; Maternal Nervous Shock or Strong Mental Impression; Maternal Intellectual Overstrain; Maternal Accident; Maternal Intemperance; Maternal Syphilis (unimportant); Premature Birth; Sporadic and Endemic Cretinism.

(*b*) *Accidental*.—Prolonged Labour with Suspended Animation; Injury during Parturition; Eclampsia; Insolation; Cranial Injury (rare); Severe Mental Shock; Cerebral Hæmorrhage and Sclerosis; Hydrocephalus; Inflammation of Brain or Meninges; Specific Fevers; Drugs (rare).

Epilepsy is present in about 20 per cent. of the cases. The Mongolian type accounts for about 10 per cent., and these children are rarely epileptic. From 5 per cent. to 10 per cent. are probably to be ascribed to one of the causes classed as accidental. Of the remainder the great majority are congenital, and include a considerable number of children born prematurely. Syphilis is of little importance as a cause, and far more cases are produced by prolonged pressure during delivery with suspended animation than by injury from the use of the forceps, which, on the contrary, helps to prevent these conditions. Twenty-five per cent. of mentally defective children are first-born, and this does not seem to be due to the smallness of the families. The children born at the end of a long family also seem to be frequently affected, but twins are not specially liable.

As regards the influence of the intermarriage or blood-relations there is nothing to show that in-breeding is in itself harmful; it is so only when the stock shows a taint which would be accentuated by in-breeding, and perhaps eradicated by crossing with another and healthy strain. Even crossed unions are exposed to similar risks, and idiocy will appear in the progeny of apparently the most unblemished families. The number of cases which are the offspring of consanguineous marriages is about 7 per cent.

From this review it would appear that the prevention of idiocy must depend very largely upon guarding as far as possible against all conditions

likely to affect injuriously the nutrition of the embryo and child, upon precluding absolutely the direct transmission of mental defects by idiots becoming parents, and upon the avoidance of marriages where there are neuroses on both sides likely to lead to a degenerate offspring.

PROGNOSIS.—Broadly speaking the developmental cases are more disappointing than the congenital, while the accidental cases are the most unsatisfactory of all. This largely depends on the natural tendency to expect more progress where the child presents regular features, a fine complexion, and a well-developed frame; whereas many of the congenital cases, though ungainly in movements and of unattractive appearance, are far more susceptible of improvement. The damage to the brain in the accidental group may leave total mental shipwreck in a body possessed of fine physical endowments. Epilepsy is a great bar to educational progress, and the paralysed cases are often very hopeless. The prospect of life is less than in normal children, especially in the epileptic and Mongolian groups. In the congenital cases the actual mental capacity must be our guide as to the future, especially the power and extent of speech and the character of the attention. Great and lasting improvement, both physical and mental, can be looked for in Cretinism so long as thyroid-feeding is maintained.

PATHOLOGY.—The following are some of the pathological conditions found in the brain: (1) hypertrophy; (2) excessive firmness of the brain-substance; (3) hydrocephalus; (4) porencephaly; (5) sclerosis following hæmorrhage; (6) abnormal simplicity of the convolutions; (7) absence of important parts; (8) old inflammatory conditions; and (9) absence or degeneration of the nerve-cells and fibres.

TREATMENT.—The treatment of idiocy consists of a judicious combination of medical, physical, intellectual, and moral agencies. It is necessary to remember that underlying the mental processes is the brain-action on which they depend. The function of the brain is closely dependent on the proper performance of the nutritive processes, which must therefore be given as free play as possible. This means that the patient must be kept in the highest possible state of health by avoiding errors of hygiene, such as cold, ill-ventilated rooms, clay-soil; and by care that the dietary is liberal, nutritious, simple, and easily digested, the meals being at suitable intervals. Regular habits of life should be cultivated, and any disorders which may occur should be corrected by appropriate medical remedies. Thus, circumcision is often desirable, and adenoid vegetations obstructing the naso-pharynx may need removal. The teeth and eyes call for special attention. Sporadic cretinism is rapidly improved by the continued administration of thyroid-preparations; once a week will often suffice in the later stages. Epilepsy demands treatment by special attention to the food and its digestion, by keeping the bowels regular (the use of an enema being sometimes necessary and most valuable), by medicinal treatment which is found suitable to the case (the bromides being as a rule most useful, though at times harmful), and by general measures for safeguarding the subject during the fits, such as a readily opened shirt, pillows stuffed with a material giving easy access to the air, &c. A regular and full allowance of sleep, and as much open-air life as possible, must be secured. Care should be taken that damp

shoes and clothes are promptly changed. The early signs of illness must be quickly observed, such as loss of appetite and abnormal body-temperature. Tonics are occasionally required, and the syrup of the hypophosphites is useful for this purpose. Alcohol is as a rule undesirable; milk should be freely used.

Medicines should not be given in food. Cleanliness should be scrupulously attended to, and daily baths are often desirable; they can rarely be given quite cold. Night-socks are often necessary in winter. In some cases regular general massage, frequent feeding, and rest in bed are necessary to promote nutrition which is suffering from restlessness and excitement. Massage is often of value in cultivating the usefulness of muscles which are too little employed. Orthopædic instruments are needed in many cases of deformity, surgical procedures being used with caution owing to the difficulties of the after-treatment. Suitable exercises and a mid-day rest on a backboard should be recommended when there is tendency to curvature of the spine, and a poroplastic jacket may also be necessary. Operative measures on the skull in the hope of relieving pressure on the brain are not to be recommended, as experience shows that they are of no use.

Having secured as far as possible the general well-being of the body, we have to devote our attention to the functions of the nervous system, the higher levels of which form the substratum of mental action. We proceed from the purely physical sensorimotor reactions upwards, from simple sense-stimuli to compounded sensations; from simple reflex automatic and rhythmic movements to co-ordinated, varied, and adapted movements; from large, coarse reactions to smaller and more delicate. This is done by choosing simple stimuli, and by their frequent repetition, such as those of touch, colour, shape, weight, or heat, by graduated movement-exercises and by simple forms of play. In this way it is sought to rouse the attention and fix it by interest. Thus by slow stages the pupil may be taught as a lesson to dress and undress himself, to use spoon, knife, and fork, to tie and button his clothes. It may be necessary to teach walking with a 'go-cart.' By degrees impressions from being merely felt come to be perceived, and perceptions become united to form ideas. Here, again, the progress is from simple to complex, from concrete to abstract. At this stage the methods of the Kindergarten become useful. Ideas of number and arithmetic are a great stumbling-block, though reading and writing are frequently acquired. Imitative drawing can be taught, but drawing as a mode of expression or as an art is almost unknown. Even in a low state of intelligence simple moral appreciations or habits are formed, and wise guidance is here very important, especially in the early periods. The child must not be spoiled, but should be disciplined to obey, and wrong-doing should always lead to some loss of pleasure. Physical punishment is unnecessary and useless; the love and approval of the teacher is the greatest reward, and its withdrawal the most effectual punishment. Punishments should not be such as to interfere with hygiene, and the appropriate methods can only be learned from the study of the individual child.

Among the *matériel* and occupations useful in school at different stages are the following:—Bean-bags; balls; bricks; hammer and nails; tying-

blocks, buttoning-sleeves; beads; groups of simple objects in which colour, number, form, and quality are illustrated and associated; paper for folding, cutting, and plaiting; sand and clay for moulding; dolls for dressing; paints and brushes; coloured chalks and chequered books; scales and weights; model money and materials for the shop-lesson; string for winding, knotting, netting; woolwork and needlework; rush-plaiting, basket-making; slöjd; fretwork; carpentering; simple gardening; simple painting and printing; bagatelle, croquet, and other simple games; drill with music, bar-bells, and dumb-bells; singing, piano, dancing, and theatricals.

The educative treatment of the mentally deficient should be begun at the earliest possible moment. Experience does not show that rapid and marked improvement is to be looked for at special periods such as the seventh and fourteenth years, as is sometimes stated; rather are these to be regarded as periods of danger to the developing mind. Speaking generally, the chief desiderata are to recognise the presence of abnormal defect as early as possible, to rescue the subject from the isolation in which his difference from normal children tends to place him; to provide, if possible, the society of other children on the same mental plane, by whom he may be regarded as one of themselves, and among whom life may seem less difficult and hopeless, and success within his reach. The life should be ordered, but varied, providing at once manifold impressions and incentives to activity, and the restraints of organised society; in this way such self-dependence and self-respect as is possible will be fostered, and the highest standard of life compatible with the mental and physical conditions maintained.

R. LANGDON-DOWN.

IDIOPATHIC (*idios*, peculiar; and *páthos*, a disease).—A term sometimes applied to a morbid condition when the antecedents giving rise to it are entirely unknown.

IDIOPATHIC MUSCULAR ATROPHY.—*See* MYOPATHY.

IDIOSYNCRASY (*idios*, peculiar; *σύνγκρασις*, mixture or constitution).—In medical language this term denotes a peculiarity of reaction, exhibited by an individual, towards certain mental or physical conditions.

Mental or nervous idiosyncrasies may be seen in response to many varieties of stimuli. For example, vision may be the channel of affection. Syncope is produced in some persons by the sight of blood; or, as is related by Prochaska, swooning may invariably occur on the sight of beetroot. As regards the sense of smell, some people are distressfully affected, in both bodily and mental ways, by the exhalations from certain animals, the cat in particular; in others, horror and fainting are induced by the odour of roses or of apples. And so on through the rest of the senses.

In another group of idiosyncrasies the higher nervous centres play no part, the phenomena being of reflex production through the spinal centres, or being due to direct poisoning of the system or of organs. Among foods or drugs swallowed, among gases or dusts inhaled, among substances brought into contact with the skin, many, harmless to the majority of men, are for this or that individual irritants or poisons. For instance, eggs, honey, sugar,

or fish may produce in certain persons gastric pain, nausea, or vomiting; strawberries may act as a most virulent poison, producing symptoms of intense nervous shock; convulsive spasms may be excited by the smell of musk or civet; asthma by the inhalation of the powder of ipecacuanha; urticaria by the eating of shell-fish, or even by the application of the yolk of egg to the skin.

Idiosyncrasies exhibited with regard to particular drugs have a special interest for the medical man. They may be of a qualitative nature, as in the production of unusual symptoms with dangerous or fatal results by anæsthetics, or in iodism; or of a quantitative nature, as in the case of opium and belladonna, minute doses of which will poison some persons, while doses of them, large enough to destroy a dozen average individuals, may be taken by one here and there with impunity.

Idiosyncrasies may be set up or modified by varying conditions of life and health. Transient oddities of susceptibility may arise in pregnancy, hysteria, and madness. These only differ in their transitory character from other idiosyncrasies, and indicate temporary modifications of reactive sensibility. Intolerance of opium may arise in some morbid states the nature of which is fairly known, for example, in renal disease, which causes defective elimination of this poison; tolerance of, or comparative indifference to, the same drug may be attained by its constant use. Age, habits, and state of body may each and all modify the reaction of any individual towards his surroundings, and may change his behaviour under the influence of drugs.

Imaginary idiosyncrasies.—Persons are not infrequently met with who declare that particular foods and medicines disagree with them. It may often be found, on investigation, that the assertion is incorrect. The obstacles offered to effective treatment by such fancies are sometimes considerable, but when the idea of their existence has been proved in any case to be unfounded, it is generally possible to evade them by tact, or to dissipate them by firmness.

WILLIAM M. ORD.

IKOTA.—*See* ECSTASY.

ILEUM, Diseases of.—*See* INTESTINES, Diseases of.

ILEUS (*εἰλέω*, I twist).—A synonym for an intestinal obstruction. *See* INTESTINAL OBSTRUCTION.

ILLUSION.—A false or mistaken perception of one of the senses, as when a person sees or hears something, and takes it to be something else. Illusions may occur in the sane as well as in the insane. *See* HALLUCINATION.

IMBECILITY.—*See* DEMENTIA; and IDIOCY.

IMMUNITY (*immunis*, exempt).

DEFINITION.—Immunity to disease may be defined as a condition of the animal body, natural or acquired, which renders it resistant to the invasion of one or more infective disorders.

GENERAL CONSIDERATIONS.—An animal or man in such a condition is said to be protected against the particular disease from which it is immune. All the disorders in which the question of immunity occurs are infective, that is, are capable of being transmitted from one animal to another by means of a contagium vivum, virus, or

primary infective agent. The question of immunity is closely bound up with the study of this primary infective agent, with its morphology, its physiological life-processes, and the modes by which it produces its pathological effects. *See* BACTERIA.

The infective agent is known in the following infective disorders occurring in man : Tuberculosis, anthrax, diphtheria, glanders, tetanus, relapsing fever, erysipelas, pus-infection, pneumonia, influenza, actinomycosis, typhoid fever, cholera, gonorrhoea, plague, Malta-fever, and malaria ; and it is in connection with some of these disorders that the question of immunity has been worked out experimentally.

In other infective disorders, such as scarlet fever, measles, small-pox, syphilis, and typhus, the infective agent is unknown, so that the nature of immunity to them is at present unsolved.

The physiological life-processes of the pathogenic micro-organisms are important to the question of immunity under two headings. For their development and growth these infective agents require a suitable medium, which, in any individual disease, is formed for them or by them from the fluids of the body. In the interstitial fluids of the tissues, and in fibrin and proteids exuded from the blood in pathological effusions, these infective agents find suitable media for rapid development and growth, and in such media they produce poisonous chemical substances, which, circulating in the body, are the cause of the symptoms, both general and specific, of infective disorders.

The poisonous products which pathogenic micro-organisms form are divisible into two classes. In one the poison is the result of the breaking up of the proteid substances dissolved in the medium in which the micro-organism lives, resulting in the formation of albumoses, and, in some cases, of non-proteid substances containing nitrogen. The other class includes substances present either in the bodies of the bacillus, or excreted by them into the surrounding medium. These bodies are frequently referred to as the *toxins*. The toxins vary greatly as regards their physiological action, and their sensitiveness to external conditions. *See* TOXINS.

In connection with immunity two points have to be considered regarding the infective agent : (1) Its degree of virulence or attenuation ; and (2) the localities in which it grows in the body in natural disease ; and with these are associated its mode of distribution, and its effect in an animal after experimental inoculation into the circulation, under the skin, or into one of the cavities of the body.

1. *Degree of Virulence or Attenuation of the Infective Agent.*—Artificial cultures of pathogenic bacteria tend to lose their virulence in the majority of instances, so that a culture, even if it has once been virulent, will, after keeping, fail to kill an animal in a short time, taking three or four more days to produce a fatal result ; and this attenuation occurs, even though the bacterium preserves its cultural characteristics. During the process of loss of virulence some bacteria undergo partial degeneration, as, for example, those of cholera and diphtheria. A virulent bacterium may also be attenuated by various methods, as, for example, keeping it at a temperature of 45° C. to 50° C. for several hours. In some cases attenuation results

from the passage of a continuous current of air through the liquid in which the bacterium is growing, and in others, by the addition of antiseptics to a medium ; both carbolic acid and trichloride of iodine have been used for this purpose. A weak virus may, in some instances, be intensified or made virulent again. The chief method by which this is done is that of passing the bacterium through a series of susceptible animals, one animal being inoculated from the one just dead. After a series has been done, an extraordinary degree of virulence of the micro-organism may be obtained, as, for example, in the cases of the vibrio of cholera, of the typhoid-bacillus, the *Bacillus coli communis*, and the pneumococcus. Another method is to inject, at the same time as the bacterium, the chemical products of another micro-organism. Thus the typhoid-bacillus has been intensified by injecting a weak culture into the peritoneal cavity, and at the same time, subcutaneously, the chemical products of the streptococcus or the *Bacillus prodigiosus*. In this case it may be said that these chemical products lower the resistance of the body, and so enable the typhoid-bacillus to grow. The infective agent which produces individual cases of disease may, in some instances, be weak, and in others virulent, and it seems probable that, for maintaining the virulence of a pathogenic micro-organism, the living body is essential.

2. *Localities in which the Infective Agent occurs in the Body.*—Three classes may be distinguished :

(a) In one the infective agent distributes itself throughout the tissues of the body. Anthrax is a type of this class : as, wherever inoculated, the bacillus passes into the fluids and tissues of the body, and is there found at death. Glanders is another example. (b) In a second class the infective agent becomes limited to the seat of inoculation, or, when it enters the body, its growth results in the formation of different lesions in the tissues. Examples of this are diphtheria and tetanus, tuberculosis and pus-infection. (c) In a third class the infective agent is chiefly found in the formed elements of the body. Thus, in leprosy, the bacillus is confined almost entirely to the interior of the cells of the leprous nodule ; in malaria, the plasmodium is found inside the red blood-corpuscle.

Immunity may be : (1) Natural ; or (2) Acquired.

1. *Natural immunity.*—Natural immunity includes those cases in which man or any animal does not contract in the ordinary course of events a particular infective disorder, as well as those cases (some of which are now well known) in which it is found difficult, and, in fact, impossible, to infect an animal with a particular disease. Such cases as these are the best examples of natural immunity. The injection, for example, of a virulent infective agent into one animal will not kill it, while a similar or even smaller dose into an animal of another species will with certainty be fatal. Warm-blooded animals, therefore, including man, may, from this point of view, be divided into two classes—those which are *susceptible* to a particular infective disorder, and those which are *refractory*.

The discussion of natural immunity in man includes many other factors besides the condition of health of the tissues of the body, such as exposure to infection, susceptibility to disease according to race, sex, and age, and the influence of climate and temperature. Man is subject to certain infective diseases (e.g. typhoid fever, cholera, scarlet fever, measles,

diphtheria, &c.) which are not prevalent in animals. Animals (domestic and farm) are subject to certain diseases (e.g. swine-plague, contagious pleuropneumonia, distemper, black leg, &c.) which do not affect mankind. Lastly, there are certain infective diseases from which both mankind and animals suffer, viz. tuberculosis, anthrax, hydrophobia, glanders and farcy, pyæmia and pus-infection, tetanus and plague. In many of these diseases the primary infective agent is unknown; the question of immunity in them must therefore remain practically open. In others, however, the virus is known, and in some well studied. Special interest attaches to the question of immunity in those diseases which are natural in both man and animals, or which are natural in man and which are infective to animals by means of inoculation of the virus, although these may not suffer from them in the natural course of events. We have in such diseases opportunities for experimentally testing the conditions producing immunity. *Tuberculosis*, of which the primary infective agent is the *Bacillus tuberculosis*, is a natural disease in man, cattle, and pigs. Goats, sheep, horses, and dogs are relatively immune to it. It is difficult, although not impossible, to produce tuberculosis in dogs by the injection of the tubercular virus: positive results are obtained with very large doses injected into the peritoneal cavity. *Anthrax*, a natural disease in oxen, sheep, and in man, is observed also in pigs, goats, and horses; but experiment has shown that adult white rats, Algerian sheep, dogs, and pigeons are difficult to infect, and are in fact refractory to the disease. To *diphtheria*—a natural disease in man—rabbits, guinea-pigs, dogs, cats, monkeys, and cows are susceptible; while rats and mice are refractory, being naturally immune to the *Bacillus diphtheriæ*. To *cholera* no animal can be said to be susceptible, although the intensified *Vibrio cholerae asiaticæ* (Koch) is fatal to dogs and guinea-pigs, but is not so active in rabbits. In many instances this natural immunity, as tested by inoculation, is not an absolute quantity: it is, in fact, a quality possessed in varying degree by the several animals called refractory to a disease. Thus dogs may be regarded as practically immune to the *Bacillus tuberculosis*, even large doses inoculated subcutaneously producing no effect. To the *Bacillus tetani* they are immune to a less degree: a large dose subcutaneously will be fatal, while a small dose will produce a mild illness ending in complete recovery. Adult white rats are refractory to the *Bacillus anthracis* only in a minor degree. If a large number be inoculated with a virulent virus, less than half will die of the disease, the remainder showing only a passing illness or no illness at all. Pigeons, too, can be killed with the bacillus, although many survive and show a lesion at the site of inoculation. It is asked, What is the reason of this immunity—what physiological difference is there between the cow and the dog, that the former is very susceptible to tuberculosis, the latter eminently refractory? or between the French, Russian, or English sheep and the Algerian, or between the young rat and the adult white rat, that the former acquire anthrax and the latter not? or that a well-bred pig is susceptible to swine-erysipelas and a mongrel refractory? The investigation of these facts is the point of the question under discussion, and has led to the discovery of important facts bearing on immunity to disease.

2. *Acquired immunity*.—In man there is evidence to show that one attack of an infective disorder protects the individual against subsequent attacks; but the truth in the matter is difficult to ascertain. There is no doubt that an attack of small-pox is protective, as the results of the now obsolete inoculation showed. It is, however, an assumption that one attack in every case of an individual disease confers immunity. There is, indeed, some evidence to show that an attack of erysipelas or of tuberculosis not only does not confer immunity, but actually predisposes to subsequent attacks. But this point of view of the subject is so hedged by difficulties that little good would come from a discussion of it. It will be best, therefore, to pass on to the question of immunity acquired experimentally. The basis of most of the experiments performed is that an attack of a disease protects against a subsequent attack, and that, although the first attack may be mild, it must not be too mild, or no protection is afforded. It will not be too much to say that all recent experiments in immunity have been based on the idea of the protection afforded by vaccination against small-pox. See SMALL-POX; and VACCINATION.

The factors in immunity and in infection are three in number: (1) the degree of virulence of the infective agent; (2) the dose of the poison; and (3) the degree of resistance of the body to the invasion of the infective agent. The body has natural defences against the invasion of micro-organisms, but these means of defence are not effective against a certain (large) dose of the poison, nor with very virulent bacteria. The natural defences of the body are: (1) an unabraded and healthy skin and mucous membrane; (2) the presence of hydrochloric acid in the gastric juice, which inhibits the growth of bacteria in the stomach, and is inimical to the growth of some pathogenic organisms, for example, the *cholera-vibrio*; (3) the natural antagonistic action of certain substances present in the liquids and cells of the body.

The natural resistance of the body may be increased by the production of artificial immunity, which may be brought about in three different ways: by using an attenuated living virus; by treatment with the chemical products of the virus; or by the injection of the blood-serum of animals made immune by one or other of the first two methods. The first two methods are practically the same, inasmuch as the bacterium acts by means of its chemical products, and these two methods are frequently referred to as *preventive inoculation*.

Preventive Inoculation.—1. Immunity may be conferred by the injection of an attenuated virus, as was shown by Pasteur in the case of anthrax. The bacillus was attenuated, and two kinds of vaccine were made. The *premier vaccin* is the weaker, and is injected subcutaneously in sheep, being followed, after an interval, by the injection of the more powerful *deuxième vaccin*. After a time the animal is found immune against anthrax; that is, the inoculation of a virulent culture of the bacillus produces no disease. Similar results were obtained with the bacillus of fowl-cholera and with the attenuated cultures of the bacilli of tetanus and of diphtheria.

2. *Immunity conferred by the Chemical Products of the Virus*.—The production of immunity by the attenuated living virus is now mainly of academic interest, since it is found that the results can be

better gauged if the chemical products of the bacterium are used instead. Thus it has been found that the chemical products of the anthrax-bacillus and of the *Bacillus pyocyaneus* can confer immunity when injected into an animal. In the case of the cholera-vibrio and the typhoid-bacillus the bodies of the micro-organism are used for injection, as in these cases the poison exists chiefly in the bacterium itself. A similar procedure is pursued with plague. In the case of the bacilli of diphtheria and tetanus the toxin is excreted into the culture-medium, and may be obtained of a high degree of virulence. Gradually increasing doses injected into the horse produce a high degree of immunity. Similar results have been obtained with certain non-bacterial poisons, namely, snake-venom and two vegetable poisons, abrin and ricin, obtained respectively from the seeds of the *Abrus precatorius* and of the castor-oil plant. The repeated injection of very small doses of these poisons into animals results in the production of a very high degree of immunity against the poison.

The Blood and Tissues in Immunity.—The study of artificial immunity produced in the manner just described has brought to light two facts: (1) The immunity is specific, that is, an animal rendered immune against diphtheria is not immune against tetanus, and *vice versa*. So with the other diseases, and even with the closely allied poisons, abrin and ricin; an animal immune against the former is not immune against the latter. (2) There exist, in the blood and tissues of these artificially immune animals, substances which are antagonistic to the infective agent or its poison. These are the immunising substances, and may be found in large quantities in the blood-serum and certain of the excretions of the body. These immunising bodies may be referred to as *anti-substances* or *anti-bodies*, and are of different natures.

The chief groups of these bodies are: (1) Antitoxins and antiferments; (2) Antimicrobial substances; (3) Agglutinins; (4) Bacteriolysins.

The *antitoxins* are substances which completely counteract the effect of the toxins. Thus, the antitoxin of diphtheria, when mixed with the toxin outside the body, prevents its physiological action, and, indeed, actually combines with it. Injected into the body after the toxin, antitoxin will counteract its effect, if the interval between the injections is not too long. A previous injection of antitoxin will confer immunity against both the toxin and the bacillus. The *antimicrobial substances* protect only against the living infective agent, and not against its poison. The *agglutinins* are substances which cause the clumping together of the bacilli when these are mixed with it, and the *bacteriolysins* are bodies which cause the dissolution of the bacteria.

See ANTITOXINS.

These substances are produced in the body as the result of the reaction of the tissues to the chemical products of the bacterium. They are all specific substances, and have an action only on the special bacterium concerned, or its poison. The existence of these bodies in the blood and tissues of animals rendered artificially immune throws great light on the process of immunity, which, from this point of view, must be considered to be due to the presence in the body of substances which are antagonistic both to the bacterium and its poison. Whether natural immunity to disease is due to the presence of such antibacterial substances is a question which

is not yet settled, and the idiosyncrasies which are shown in the invasion of infective disease in various classes of animals have not been completely explained by the researches as yet performed. In some cases, where disease occurs naturally in animals and not in man, or *vice versa*, there is only a partial immunity. Although no animal suffers naturally from cholera, yet the intensified vibrio of cholera is fatal to dogs and guinea-pigs; thus, there may be immunity against the natural disease, and not an immunity against inoculation. There are, however, instances of natural inoculation-immunity. Thus dogs are highly refractory to the inoculation of tuberculosis, pigeons also are immune to the inoculation of anthrax, and mice are refractory to the diphtheria-toxin. It may, in the future, be found that specific antibacterial substances are present in such conditions, but account must be taken of the existence of phagocytosis, and though this cannot be held, as it was formerly, completely to explain the phenomenon of naturally acquired immunity, yet the fact that certain living cells of the body do ingest living bacteria, and may destroy them, is an important one in considering immunity. *See PHAGOCYTOSIS.*

Immunity and Cure of Disease.—The question of immunity is closely connected with that of the cure of infective disease. Immunity is the successful resistance of the body against the invasion of an infective disease; cure is the prevention of further progress of the disease after the symptoms have already appeared. Many cases of infective disease get well, even if no specific treatment is employed, and the natural subsidence of an infective disease may, as the result of modern research, be reasonably ascribed to the production of immunity, and more particularly to the formation of antibacterial substances, as the result of the reaction of the body against the action of the bacterial poison. That such substances are formed in the body during the course of a disease is shown by the presence of agglutinins in the blood of patients suffering from cholera or typhoid fever. Moreover, the injection of antitoxins after the disease has begun in some instances leads to a cure of the disease, that is, to a cessation of the growth of the bacterium. Thus, in diphtheria, more particularly in the early stage, the injection of the antitoxic serum stops the spread of the membrane, and so relieves the symptoms of the disease. It, moreover, neutralises in the body any of the bacterial toxin which has not yet combined with the tissues. In tetanus a similar result may be obtained, although the effect is not so marked. Whether, in cases of diphtheria treated by antitoxin, the patient survives or not, depends on the amount of toxin which has combined with the tissues previously to the injection of the antitoxin. If a fatal dose is already in combination with the tissues, no treatment by antitoxin can prevent a fatal result, although it hinders the further progress of the active disease. Cases of tetanus are not so amenable to treatment by the antitoxin, owing to the firm combination of the toxin with the tissues, and to the usually late period at which the patient comes under treatment.

SIDNEY MARTIN.

IMPERATIVE IDEAS.—*See INSANITY.*

IMPETIGINODES.—Impetiginous; that is, having the character of impetigo; hence, eczema impetiginodes. *See IMPETIGO.*

IMPETIGO.—Two diseases are described under this title: *Impetigo contagiosa* and *Impetigo herpetiformis*; but the term is generally limited to the first of these.

Impetigo Contagiosa.—**CLINICAL FEATURES.** The disease appears as slightly erythematous raised points on the skin, which rapidly become vesicular. These lesions may remain small in size, or by coalescence produce bullæ. The vesicles and bullæ are very superficial, often imperfect and covered by the upper layers of epithelium only. They at first contain almost clear serum, but rapidly become sero-purulent and rupture, and the collapsed roof of the vesicle, along with coagulated exudation, pus, and desquamated epithelium, give rise to the crust which is the characteristic feature of the disease. The crusts are irregular in shape, though more or less rounded in outline, and, unless subject to undue irritation, are surrounded by no more than the faintest margin of erythema. In the ordinary course of the lesion the crust dries in a few days, falls off, and leaves a reddened surface, which rapidly loses its pigmentation, and heals without the formation of any scar. The discharge from each patch is contagious, so that the disease tends to spread at the margin, and to give rise to new foci in the neighbourhood, until large areas of the skin may become infected. Neighbouring lymphatic glands readily enlarge and, unless care is taken, suppurate. The onset of the disease may be marked by febrile phenomena, especially in the debilitated, and in cases of extensive and rapid infection. As a rule, however, the general symptoms are very slight.

The disease is most prevalent in children, but is frequently seen in adults, especially those in charge of affected children. It appears most commonly on the parts of the body most exposed to contagion, especially the face and the scalp, but is also common on the fingers, hands, arms, and legs. From these situations the virus may be conveyed by the fingers or clothing to any part of the body. Epidemic outbreaks of the disease occasionally occur in crowded localities and schools. The disease usually runs a mild course, but in debilitated children symptoms of septic absorption may arise, and the individual lesions assume an ulcerated and gangrenous type. These cases may end fatally.

Another form, showing itself as primary pustules situated around the follicles of the skin, is known as the 'Impetigo of Bockhart.' This form of the disease is supposed to have a follicular origin, and to be characterised by a greater tendency to destruction of the skin.

PATHOLOGY.—The disease may be considered as the characteristic example of the effects of the inoculation of pyogenic organisms on a susceptible skin. In the lesions of the disease many forms of bacteria have been discovered, but the most important are the cocci of suppuration, namely the *Staphylococcus pyogenes aureus*, the *S. pyogenes albus*, and the *Streptococcus pyogenes* (see **PYOGENIC BACTERIA**). Usually more than one of these species of bacteria are present, but the organisms most commonly found are the staphylococci, and especially the *Staphylococcus aureus*. In addition to these, white cocci with mildly virulent characters of the type of the *Staphylococcus epidermidis albus* (*S. cutis communis*) are usually present, but this organism cannot yet be definitely distinguished from the *Staphylococcus pyogenes albus*. The *Bacillus pyocyaneus* and the *B. coli communis* have also

been isolated. Sabouraud and some other observers state that in the vesicular stage of impetigo, while the contained serum is clear, the *Streptococcus pyogenes* is invariably present, and no other organism; that secondary infection of the lesions by staphylococci occurs at an early stage; and that these staphylococci grow rapidly and obscure the streptococci present. The same investigators hold that the primary pustular lesions in the type of impetigo described by Bockhart contain staphylococci from the commencement, especially the *Staphylococcus aureus*. The results of these investigations are held to support the hypothesis that the ordinary type of impetigo is the immediate result of the inoculation of the *Streptococcus pyogenes*, the disease being subsequently complicated by secondary infection with staphylococci; whereas impetigo with primary pustular lesions (Bockhart) is due to the primary inoculation of staphylococci, especially the *Staphylococcus pyogenes aureus*.

In this way epidemics of the disease may be easily explained as well as varieties such as that known as 'Football Impetigo.' It is still uncertain whether these lesions can arise by the direct inoculation of organisms from the outside, whether they must be derived from individuals similarly affected, or whether the bacteria already existing in the skin may under certain conditions acquire sufficient virulence to produce the disease.

TREATMENT.—The purulent crusts must first of all be removed. This is best done by softening them with warm antiseptic washes or fomentations. In the case of the scalp, if necessary, the hair must be cut short. Any pediculi present on the body or in the clothing must be destroyed. Careful washing with soap and water may be employed, followed by the use of boric acid in the form of lotions or of fomentations. After removal of the crusts, dressings must be used so as to render the skin as aseptic as possible. One of the most efficient methods is by the use of mercurial ointments, and of these the Ung. Hydrarg. Nitrat. Dilut. is probably the best. The ointment should be used in the first instance spread on lint and applied to the surface; subsequently, as the lesions begin to heal, it may be gently rubbed into the skin. The dressings should be renewed twice a day, or as often as may be necessary to prevent the crust re-forming.

Many other forms of treatment by means of antiseptic remedies may be devised, such as by carbolic acid, perchloride of mercury, ammoniated mercury, and β -naphthol. In the case of debilitated patients, care must be taken to improve the general health by cleanliness, good hygienic conditions, and a generous diet.

Impetigo herpetiformis.—This name has been applied by Hebra and Kaposi to a condition in which groups of pustules appear on the skin, in recurrent outbreaks, attended by severe constitutional symptoms, such as rigors and high fever. Its course seems to be invariably fatal, but its pathology and aetiology are unknown. By some observers the disease is considered to be of virulently septic origin, while others have included it in the category of dermatitis herpetiformis (see **HYDROA**). This form of disease does not seem to have been observed by British dermatologists.

JAMES GALLOWAY.

IMPOTENCY (*in*, not; and *potens*, capable).—**SYNON.**: Fr. *Impuissance*; Ger. *Impotenz*.

DEFINITION.—Impotency may be defined as incapacity in the male for copulation, and is to be distinguished from sterility, that is, incapacity for procreation. Cases of impregnation without penetration have been recorded, but, as a rule, impotency involves sterility. A man may be sterile without being impotent.

Impotency may be complete or partial, permanent or temporary.

CAUSES.—Deformity, congenital or acquired, of the external genitals may produce impotency. Extreme degrees of epispadias or hypospadias, or a permanent rudimentary condition of the penis, may cause it. Elephantiasis of the penis or scrotum, a large hydrocele of the tunica vaginalis, a large irreducible scrotal hernia, or tumours, benign or malignant, of the penis may mechanically hinder penetration. Cicatrices, resulting from wounds or disease of the penis, a rigidly contracted frenum præputii, or even a permanently adherent prepuce may cause such distortion of the organ during erection as to render copulation impossible.

Usually, however, impotency is of nervous origin, but may be classified as *psychical*, *irritable*, and *paralytic*.

Psychical impotency results from the undue pre-dominance of the cerebral inhibiting centres. In newly married men, who have previously led chaste lives, it may be induced by want of self-confidence. In such cases a tonic may be prescribed, and the patient be directed to abstain from all attempts at intercourse while under treatment, but encouraging assurances will do more in effecting a cure than any sort of medical treatment. In cases where excessive venery or masturbation has been practised, there may be diminished excitability of the lumbar centre; but this condition is usually of very brief duration. Impotency may be experienced in attempted intercourse with one person and not with others.

Irritable impotency is the result of undue excitability of the nervous centres. It occurs after habitual masturbation or excessive venery. The semen is ejaculated before penetration has been effected, and the erection speedily subsides.

Paralytic impotency may be due to injury or disease of the nervous system. Diseases and injuries of the spinal cord, producing paraplegia, necessarily prevent active copulation; but if the spinal lesion be above the erection-centre, erection and connection might be possible, the man being a passive agent. Cases are reported where even impregnation has occurred in such conditions.

Some drugs are credited with producing impotence. Arsenic, when taken for a long time, has, in some instances, produced this effect, but virility is regained when the drug is discontinued. Opium-eating and excessive indulgence in tobacco have been accredited with similar effects. Diuretics, as the nitrate of potassium and bicarbonate of sodium, are well known to act as anaphrodisiacs.

Virility is more or less affected by constitutional diseases. Few complaints have greater influence in impairing the generative functions than those of the kidney. In irritative dyspepsia, with deposits in the urine of earthy phosphates or oxalate of lime, there is generally some inability. In diabetes, gout, and chronic hepatic diseases the reproductive organs are weak and often quite inactive, but may recover tone as health is restored.

Impotency sometimes occurs in middle life with-

out any obvious cause. Such persons have been observed to grow sleek and corpulent, to have a scanty beard, and to be indisposed to active muscular exertion. In general they evince no unhappiness at their altered condition. In atonic impotency, the external organs afford indications of the want of power. Not only are the testicles soft and flaccid, from the absence of blood in the vessels and sperm in the tubes, but the penis is small and shrivelled, and the glans relaxed.

TREATMENT.—In an atonic state of the organs, in which the erections are feeble, unstable, and insufficient, ten to fifteen minims of the tincture of cantharides may be given every three or four hours for a short time before the occasion arises for the exercise of the sexual functions. Diluted phosphoric acid, phosphate of iron, strychnine, and ergot of rye are remedies which may be given in impotency. The conditions to which these aphrodisiac remedies are chiefly applicable is when the intromittent organ is but feebly excited, and does not maintain the physical state necessary for penetration, during the period of congress. Such torpidity may exist in persons in whom desires are at times strongly felt, and the functions of the testicles properly performed. In these cases, also in timid persons, and in others whose organs are inexcitable from long disuse, stimulating treatment may conduce to success, and insure confidence for the future. But these remedies exert no influence in a constitutional apathy of the sexual functions. They have rarely, also, more than a temporary effect; and in persons advanced in life, when the parts, having fulfilled their office, are experiencing their natural decline, they operate injuriously, and tend to produce congestion of the prostate and local disease. In those cases in which the sexual organs are weakened or prematurely exhausted by excess, they are likewise hurtful, as well as fruitless. After such abuses a period of repose is required; and by the avoidance of all sources of excitement, and by diet and remedies adapted to invigorate the body, such as the preparations of iron, a gradual restoration of the procreative functions may be hoped for. Electricity is a remedy sometimes employed in impotency, but is rarely of much service. See STERILITY IN THE MALE.

IMPULSE (*impello*, I thrust forwards).—A sensation of a stroke communicated to the hand, for example, by the action of the heart or by the pulsation of an aneurysm; or by the sudden movement of a fluid when agitated in any way (see PHYSICAL EXAMINATION). The term is also employed in connection with a mental condition in insanity. See INSANITY, Varieties of.

IMPULSIVE INSANITY.—See INSANITY, Varieties of.

INCARCERATION (*in*, in; and *carcer*, a prison).—That condition of hernia in which it cannot be reduced, on account of obstruction at the neck of the sac or from some other cause. See HERNIA.

INCOHERENCE (*in*, not; *con*, together; and *hæreo*, I stick).—Inconsecutive or 'wandering' thought, as expressed in speech. See CONSCIOUSNESS, Disorders of.

INCOMPETENCE (*in*, not; and *competo*, I meet accurately).—In its general sense this term

signifies inability of a part to perform its functions. It is mainly applied to imperfection in the closing apparatus of an orifice, such as the valves of the heart (insufficiency) or the pylorus. See HEART, Valves and Orifices of, Diseases of.

INCOMPRESSIBLE.—Incapable of perceptibly yielding to pressure. Usually applied to the pulse. See PULSE.

INCONTINENCE (*in*, not; and *contineo*, I hold).—In medical language incontinence signifies inability to retain the urine or fæces, so that they are discharged involuntarily. See DEFÆCATION, Disorders of; and MICTURITION, Disorders of.

INCRUSTATIONS.—See CONCRETIONS.

INCUBATION (*incubo*, I hatch).—The *period of incubation* is the stage which intervenes between the reception of an infection into the organism and the first manifestation of the disease. Such an interval must occur in every infectious disorder, but the term is not usually employed except in relation to the acute specific diseases in which a more or less well defined period of incubation is observed.

A knowledge of the ordinary duration and of the extreme limits of the period of incubation may be of some assistance in diagnosis when the facts as to exposure are known, but its chief importance lies in the power which it confers of preventing the spread of disease in a community. For example, in a well-managed boarding school, the medical officer has information as to the infectious diseases from which each pupil has previously suffered; and, on the occurrence of a case of such a disease, he can ascertain with approximate accuracy the pupils with whom the patient has been in close relation, and, among these, those who have not suffered from the disease in question. Such information, though not absolutely trustworthy, is of value as indicating the zone of danger. Such 'contacts' should be kept under observation for the period of incubation of the disease, since the immediate recognition of the earliest symptoms of an attack may enable the medical officer to prevent new cases from becoming fresh foci of infection. The medical officer should also know when the disease begins to be infectious, whether, that is to say, its infection is easily conveyed during the period of incubation, and in the very earliest stages or development of the symptoms. For example, in the case of measles, which is a typical example of a specific disease infectious at the very earliest stage, the first case will probably not be recognised and isolated until the patient, in an infectious state, has been in contact with his school-fellows for at least twenty-four hours, and not improbably for a good deal longer. The number of 'contacts' will therefore in the ordinary course of school-life be considerable, and some of them will already be in the first, the second, or even the third day of incubation when the first case is discovered. On the other hand, in a disease such as scarlet fever, which is less infectious in the early stage, and in which, moreover, the sudden onset usually leads at once to a complaint of illness and incapacity for exertion, isolation can generally be effected at an early date, and the number of 'contacts' is less. The system of isolating 'contacts' has been carried out on a large scale in dealing

with plague in India, and has apparently been among the most effective of the preventive measures taken. When the patient is convalescent it becomes the duty of the medical adviser to determine when the risk of infection has ceased, and when therefore the convalescent person may be released from isolation. The answer to this question is very much complicated by the fact that infection may be retained in clothes and furniture, and that the disinfection of these is only effectual when skilfully carried out with suitable apparatus (see DISINFECTION). The pathological processes which occur in the body during the period of incubation are discussed in the articles on BACTERIA; IMMUNITY; and INFECTION.

The duration of the incubation-period is not constant, although in some diseases, as in small-pox, the variations are within very narrow limits. The circumstances which may account for these differences between individuals are variations in the resistance of the individual, the virulence of the virus, and the dose of the virus. (i.) There is little evidence that any idiosyncrasy of the individual influences the period of incubation; the general condition of health appears to determine the result of the conflict between the infective agent and the germicidal powers of the organism, but not, to any constant or considerable extent, the duration of that struggle. When an infective agent is once admitted, one of two things usually happens: either it is destroyed by the cells and fluids of the body, or it increases and produces an attack of the disease. There is some evidence, however, showing that the infective agent may occasionally remain latent for considerable periods, inhibited in its growth, but not destroyed; in such cases the incubation-period will be proportionately prolonged. Any circumstance which causes a lowering, local or general, of the resistance of the tissues may subsequently permit the growth of the infective agent. The onset of diphtheria may in this way be determined by a common cold, that of pneumonia by a blow, and, according to Broadbent, that of typhoid fever by a preceding influenza. (ii.) There is very little direct evidence concerning the effect of variations in the virulence of the virus. On the whole it seems probable in the case of typhoid fever, scarlet fever, and diphtheria that the more virulent the type of the disease the shorter will be the period of incubation. (iii.) The importance of the dose of the virus varies a good deal in different diseases, and is greatest in typhoid fever and diphtheria.

The further question whether some of the sequelæ of certain of these diseases, as, for instance, the discharge from the nose or ears after scarlatina or diphtheria complicated by rhinitis or otitis, may not continue to be infective long after the acute stage of the disease itself is past, is one that cannot be answered with confidence at the present time. In the case of scarlet fever, Simpson has suggested that these discharges, though not themselves due to a specific cause, may become the vehicle for the infective agent if the patient be retained in hospital in association with persons suffering from the disease in its acute stage. It is impossible to lay down any hard and fast rule as to the duration of the infection. Every case must be judged on its merits, having regard to all the surrounding circumstances. All that can be done is to indicate in a general way a minimum period during which a patient must be considered to remain a source of danger to susceptible

persons. This period may certainly be very much exceeded in some cases.

As a general rule the patient presents no symptoms during the period of incubation, and considers himself to be in his usual health. Some feeling of indisposition or fatigue may be experienced in cer-

tain instances, and is perhaps the rule in typhoid fever, but in diseases characterised by a sudden onset, of which scarlet fever is a good example, the patient may feel and seem perfectly well until seized with the headache, vomiting, or other symptom which is the first manifestation of the disease.

Disease.	Incubation Period.			Period of Isolation of Patient (Minimum).	Period of Observation of 'Contacts.'
	Usual.	Minimum.	Maximum.		
Cholera . .	4 to 5 days	a few hours	6 days	Until evacuations are free from the specific microbe	7 days
Dengue . .	4 days	a few hours	5 days	—	1 week
Diphtheria . .	2 days	—	7 days	For 4 weeks at least, or until sore throat (of any kind) or mucous discharge have ceased and the B. diphtheriæ is proved to be absent 'not less than 3 days after the discontinuance of local antiseptic applications'	12 days
Enteric fever . .	10 to 14 days	8 days	23 days	To end of 2nd week of convalescence. Urine must not contain B. typhosus	3 to 4 weeks
Influenza . .	3 days	1 day	5 days	Until convalescence is complete, about 10 days	6 days
Measles . .	14 days	7 days	18 days	Until desquamation and cough have ceased, or 3 weeks at least after rash	18 days if free from coryza
Mumps . .	21 days	14 days	25 days	Until all swelling has subsided, 4 weeks at least	25 days
Plague . .	3 to 5 days	12 hours	10 days	One month, or until faces and urine and discharges, if any, are free from B. pestis	14 days
Pneumonia . .	? 2 days	a few hours	6 days	—	1 week
Rubella . .	14 days	5 days	21 days	Until desquamation has ceased, 2 to 3 weeks altogether	3 weeks
Scarlet fever . .	2 days	1 day	7 days	Until desquamation has ceased and throat is well, 6 to 8 weeks	2 weeks
Typhus fever . .	12 days	—	—	3 to 4 weeks	2 weeks
Varicella . .	14 days	13 days	19 days	Until all scabs have fallen off	18 days
Variola . .	12 days	8 days	15 days	Until desquamation has ceased and all scabs have fallen off	12 days
Whooping-cough	8 days	2 days	12 days	Five weeks from beginning of whooping, or until spasmodic cough and whoop have ceased, for 2 weeks	2 to 3 weeks
Yellow fever . .	3 to 4 days	Less than 24 hours	7 days	—	8 days

DAWSON WILLIAMS.

INDIARUBBER-MAKERS.—See OCCUPATION-DISEASES.

INDICANURIA.—Two precursors of indigo are met with in urine, viz. indoxyl-sulphuric and indoxyl-glycuronic acids. The so-called urinary indican is an idoxyl-sulphate, and must be distinguished from the indican of plants, which is a glucoside. Indoxyl-glycuronic acid is a less stable substance, and by its decomposition indigo-blue is sometimes spontaneously formed, especially in alkaline urines, and is deposited as an amorphous or crystalline sediment or floats as a scum. In rare instances it has been met with as a constituent of calculi.

In normal human urine the amount of indican present is very small, but in morbid conditions the quantity is often conspicuously increased. Urines rich in indican sometimes have a deep-brown colour, which has been ascribed to higher oxidation-products of indoxyl. Suspended indigo-blue may give to the urine a bluish tint.

When the urine is boiled with hydrochloric acid and an oxidising agent, such as a few drops of a solution of bleaching-powder, indigo-blue is formed and varying amounts of indigo-red; these pigments are readily extracted by chloroform, which acquires a blue or purple colour and shows a characteristic spectrum.

Indoxyl is formed by the oxidation of indol, and the urinary indoxyl-compounds have their origin in the decomposition of proteids by the intestinal bacteria. When such proteid decomposition is in-

creased, or when the conditions are unusually favourable to the absorption of its products, as when there is obstruction, especially of the small intestine, the excretion of indican is increased. On the other hand, indican has been found to be absent from the urine of new-born infants in the earliest days of life, before the intestines have become the seat of bacterial activity.

Clinically, gastric dilatation, ulcer and new-growths, peritonitis, intestinal obstruction, wasting diseases, such as tuberculosis, and enteric and some other fevers, are among the morbid conditions which are most apt to be attended by an increased excretion of indoxyl-compounds in the urine.

INFANTS, Diseases of.—There are few disorders which can be said to be peculiar to infancy and childhood. The diseases to which children are liable are, as a rule, those which attack older per-

sons, and present the same pathological characters. But disease as it occurs in children does yet require especial study, for the symptoms by which it is accompanied often differ widely from those met with in adults.

GENERAL CHARACTERS.—The most striking peculiarity of childhood is the marked excitability of the nervous system. A fragment of indigestible food, for example, may produce high fever, or alarming agitation, and even throw the child into convulsions; a slight irritation of the larynx may produce severe spasm, and simulate for the time the symptoms of diphtheria. The beginning of acute disease is almost invariably accompanied by profound general disturbance; but disturbance as profound may be excited by the simplest functional disorder, so that the severity of the symptoms is no guide at all to the severity of the lesion with which we have to deal. In all cases, therefore, it is of importance if possible, to pick out the local symptoms—those, namely, which point to mischief of any special organ—and separate them from others which are expressive merely of the general distress. Such local symptoms are the cough, rapid breathing, and active nares which point to acute lung-disease; the squinting and immobility of pupils which are so characteristic of cerebral affections; and the peculiar jerking movement of the legs, which, combined with hardness of the abdominal muscles, betrays the existence of colic. Such local symptoms are not, however, always to be discovered, and even if present may not furnish trustworthy indications; for so close is the connection in the young child of distant organs with one another that the organ from which the more definite symptoms appear to arise may not be the organ which is actually the seat of disease. The two organs which are most frequently found to present these deceptive manifestations are the stomach and the brain. Vomiting is a common symptom at the beginning of every acute disease, and in many children any casual disturbance is apt to be attended by it. In some cases of pneumonia, again, notably those in which the inflammation is seated at the apex of the lung, headache, vertigo, delirium, and stupor may be so marked that the ordinary symptoms of the disease are completely obscured, and the case is mistaken for one of meningitis. Again, the violent nocturnal delirium so often excited by the irritation of worms in the alimentary canal must be within the experience of all.

The nervous excitability of children, and its influence upon the system generally, are well illustrated by the high temperature noticed in many children on the first evening after admission into the wards of a hospital. The elevation varies in degree in different subjects; but if the patient be not a mere infant, it is usually over 100° , although the complaint be one not ordinarily attended by pyrexia.

Perhaps, however, the most familiar instance of the impressibility of the nervous system is seen in the case of convulsions. A 'fit' in the child has a very different meaning from a similar attack in the adult. In the latter it is usually evidence of a grave centric lesion, and its occurrence occasions the greatest anxiety. In the child, on the contrary, it is a common expression of the perturbation of the nervous system, set up in response to some excentric irritation, and often, as in the case of the onset of acute disease, is analogous to the rigor which ushers in an acute attack in older persons. Sometimes, it is

true, convulsions are produced in the child, as in the adult, by severe cerebral disease; but in such cases the fits are frequently repeated, and are succeeded by rigidity, paralysis, and other signs of centric irritation. See CONVULSIONS IN CHILDREN.

The impressibility of the nervous system is increased by causes which produce a sudden depression of strength, such as a bad attack of diarrhoea, or loss of blood; and in one chronic disease—rickets—the nervous irritability is very great. The effect of chronic wasting upon the child is, however, usually to produce an opposite result; and under the long-continued influence of enfeebling disease the excitability of the nervous system becomes gradually less and less manifest, until it finally disappears almost entirely. It is of importance to the practitioner to bear this fact in mind, for in a child much reduced by chronic illness, the presence of an intercurrent acute complication—such as inflammation of the lung—may be indicated by very few symptoms, the system having become almost insensible to nervous impressions.

Another peculiarity which strikes the attention of any one accustomed only to disease as it occurs in the adult is the vast preponderance in infantile disorders of mere disturbance of function, and the disastrous consequences which may ensue from such derangements. Infants rapidly part with their heat, and are easily chilled. They are therefore excessively sensitive to changes of temperature. A catarrh is a common ailment in the young child, and is attended by various dangers according to the part of the mucous tract which is affected by it. Gastric catarrh with violent and repeated vomiting, and intestinal catarrh with uncontrollable diarrhoea, are answerable for a large proportion of the deaths among young children during the warmer months. In less severe cases the gradual failure in nutrition which results is a common cause of wasting; such cases may end fatally. In the autumn and winter the bronchial mucous membrane is more frequently attacked. However apparently slight may be the catarrh, a weakly infant is always exposed to the danger of collapse of a considerable portion of the lung; and such an interference with the respiratory function is often a cause of sudden death.

It is in consequence of this frequency of functional derangements, and their dangerous character, that *post-mortem* examinations in infants so often fail to show any appearances explanatory of the cause of death.

CLINICAL EXAMINATION.—The clinical examination of young children requires tact and patience. The patient cannot himself describe his symptoms, but all necessary information can be gained from the parents. Mothers are, as a rule, good observers, and allowing for their natural anxiety and a slight tendency to exaggeration, their statements can usually be relied upon. We can thus learn the previous state of the child, the exact date at which his symptoms began, and the order in which they appeared. Infants should be always stripped for examination, so that the whole body may be exposed to view. Before, however, ordering the removal of the clothes, we should be careful to satisfy ourselves upon certain points which can only be properly observed while the child is in repose. Thus, in order to count the pulse and respiration, perfect quiet is indispensable, for the least movement quickens the heart's action, and alters the rapidity of the breathing. At the same time the

London Hospital.

HOW TO BRING UP INFANTS.

1. Keep them warm. Let the clothing be warm (*i.e.*, flannel or woollen), and not tight. Children should wear stockings nearly up to the knees, and frocks well up to the neck, with long sleeves. Give them plenty of fresh air; take them out whenever the weather is fine. Wash the child all over with warm water and soap daily. If possible let the child sleep in a cot by itself. Open the windows at least twice a day.

FOOD.

2. If the mother has plenty of breast-milk, the child should *not have any other food whatever*, until it is seven months old. It must be suckled every two hours during the first month, and the interval gradually increased, so that at the end of three months the child is suckled every three hours. *Too frequent suckling is a common cause of the sickness of infants.*

3. If the mother has only a little milk, let the child have it; and in addition milk mixed as directed in Rule 4. Except when ordered by a doctor, *do not on any account give the child any baked flour, arrowroot, corn flour, biscuits, tops and bottoms, or any so-called "infants' food" before it is seven months old.* It is a good plan, if the mother has only a little breast-milk, that she should drink a cupful of cow's milk half-an-hour before suckling.

4. If the child must be brought up entirely by hand, it should be fed out of a bottle with cow's milk warmed and diluted. Fresh cow's milk must be used: during the first month it must be diluted with at least twice as much water or, better still, with lime water or barley water* in the same proportion, if the milk be of good quality. A small quantity of *white* sugar must be added to each bottle. As the child gets older, the proportion of milk must be gradually increased. The milk should always be boiled before being used. This is especially important in the case of infants under three months old, and in summer.

* Barley water is prepared as follows:—Two tea-spoonsful of pearl barley to a pint of cold water, boiled down to two-thirds of a pint, and then strained through muslin. A fresh quantity must be prepared at least twice a day.

5. If cow's milk cannot be digested after a fair trial, condensed milk may be given—one tea-spoonful to four or five table-spoonful of water which has been boiled, *but after a month another attempt should be made with fresh cow's milk.*

6. The best kind of bottle is the old fashioned straight one with an indiarubber teat, and without any tube at all. It is quite impossible to prevent corks and tubes from becoming foul and turning the milk sour. When the child has finished its meal the bottle must be rinsed, and placed in clean water until again required. Once a day it should be carefully cleaned with hot water in which a little soda has been dissolved, and then rinsed with water and a few tea-leaves. On no account must the milk that remains, after the child has finished, be used again. A fresh quantity must be prepared for each time of feeding.

7. When the child has reached the age of eight months, it may have one or two meals a day of milk thickened with one or other of the following malted foods, viz.: Allen and Hanbury's, Mellin's and Savory and Moore's. Or Chapman's entire wheaten flour may be used: to prepare this, make a tea-spoonful of the flour into a paste with cold water, pour half a pint of boiling water on it, and let it simmer for twenty minutes, constantly stirring; then add it to the milk, which must be warmed. The other meals should be of milk only. The amount of these foods used may be increased as the child grows older. As a rule, the child should be gradually weaned at ten months' old. At eight months the child may have broth or beef-tea, in addition to the milk. At ten months give fat bacon, the yolk of an egg lightly boiled or beaten up, or a little milk pudding. At eighteen months, give a little meat every day scraped or pounded into soft pulp; or a little mashed potato with gravy. Cheese, beer, or spirits should never be given to children.

**** IT IS A GREAT MISTAKE TO GIVE CHILDREN UNDER TWO YEARS OLD "JUST WHAT THE PARENTS HAVE." IT IS A GREAT MISTAKE TO GIVE THEM TEA INSTEAD OF MILK. ON NO ACCOUNT GIVE BABIES TEETHING POWDERS AND SOOTHING SYRUPS.**

temperature can be taken by the thermometer in the rectum. The whole body should then be examined for spots or swellings; the condition of the skin noted—whether dry or moist; the fontanelles examined; and the state of the abdomen ascertained, including the size of the liver and spleen. If the child cry at the time, we mark the character of the voice, for hoarseness is an early sign of congenital syphilis.

In the physical examination of the chest in a child, it is important: to percuss the two sides at the same period of the respiratory movement, that is, during expiration or during inspiration; to strike gently with *two* fingers, for by this means a larger volume of sound is brought out, and slight dulness is more easily detected; to use a stethoscope instead of the unassisted ear, in order to limit the area listened to; and to manage so that the child's mouth be open during auscultation, so as to hinder the transmission of sounds from the throat. In an infant the back is best examined by placing the child on the nurse's left shoulder, with his left arm round her neck. If the chin be now depressed by the nurse's hand on the child's head, the muscles of both shoulders are relaxed. The front and sides of the chest can be examined as the infant lies on his back. We must remember that the breath-sounds, especially that of inspiration, are of a more blowing quality in the child than they are in the adult; and that there is naturally less resonance at the right base, on account of the proportionately greater size of the liver.

At the end of the examination the mouth should be looked at for signs of aphthæ or thrush; and the condition of the gums and naso-pharynx should be ascertained. Lastly, the throat is to be inspected—depressing the tongue with the handle of a spoon. If there be disorder of the digestive apparatus, such as sickness, constipation, or diarrhoea, it must not be forgotten to examine the discharges carefully. The urine should not be overlooked.

TREATMENT.—In all cases, especially if the patient be an infant, it is important to inquire into the hygienic and dietetic arrangements to which the child is subjected. Children, as a rule, respond well to treatment. This may be explained partly by the large proportion of mere functional derangements in the illnesses to which they are subject, and partly by the state of constant change through which the body is passing; growth and development are active in organs, and the tendency is to repair. The term 'treatment,' however, includes far more than the mere giving of physic. A complete change in all the influences acting upon the patient—a reconstruction of the dietary, and a reformation in the hygienic arrangements, especially with regard to air, light, and clothing—will often prove of immense service, and be of far more value than actual drug-giving in furthering the recovery of the child.

In the treatment of acute illness we must remember that young children cannot bear lowering measures; but we must not therefore rush to the opposite extreme, for unless suffering from temporary exhaustion, they are far from being benefited by profuse stimulation. In the beginning of acute inflammatory diseases stimulants are injurious. Even in chronic ailments, such as rickets, where a certain amount of alcohol is often of service, wine should be given with caution, and its effects upon the digestion carefully watched; it can only be given with

advantage so long as it improves the appetite, and increases the digestive power.

With regard to medicines little need be said in this place. It may be remarked that, on account of the tendency to acid dyspepsia in all children, alkalis are of especial service; and that they should be always combined with an aromatic, on account of the value of the latter in stimulating the alimentary mucous membrane, and relieving the flatulence and other painful consequences of indigestion. It is important also to remember that children are wonderfully tolerant of certain drugs, while they bear others very badly. Belladonna may be given to infants and children in comparatively large doses. They are also more tolerant of arsenic than their elders. To the action of opium, however, they are excessively susceptible, and the drug should be given—to infants especially—with extreme caution.

EUSTACE SMITH.

INFANTS, Feeding of.—See **DIET**; and **ATROPHY**.

INFARCT (*infarcio*, I cram in).—An infarct is a firm wedge-shaped patch of tissue, found in certain organs as the effect of arterial embolism, or a marked diminution (more than 75 per cent.) of the pressure in the supplying artery. See **EMBOLISM**.

INFECTION.—Before the nature of infective processes was understood and when, owing to the difference in the length of incubation-periods and the different results of infection, there appeared to be some difference in the method of transmission of infective disease from patient to patient, it was natural that an attempt should be made to distinguish between those diseases in which there was direct transmission from patient to patient and those in which the transmission was indirect. Again, direct transmission was supposed to be either by direct contact, in which case the disease was spoken of as being 'contagious,' or through the atmosphere, when it was said to be 'infectious.' But since it is now known that, in all infective diseases, there is an infective element which can multiply, sometimes outside the body, and usually inside, it is better to include all these diseases in one great group in which the *materies morbi* can be transmitted by 'contagion,' the principal factor being the multiplying *materies morbi* which, transmitted, directly or indirectly, from patient to patient and finding suitable conditions for its development, is capable of growing and of setting up a specific infective disease. It must be insisted on at the outset that although most of the infective diseases are transmissible from one individual to another—and this group is gradually absorbing all the infective diseases—there are a few which up to the present have not been demonstrated as being transmissible, or as being transmissible only through an intermediate host. For example, malaria and relapsing fever are sometimes said to be non-transmissible. That they do not pass directly from patient to patient may be readily enough accepted, but it is now recognised in the case of malaria, and it is possible that a similar statement holds good also of relapsing fever, that on the parasite being introduced into the blood directly from individual to individual, or being first taken by the mosquito into its digestive cavity, and later, after certain developmental changes, being injected through the proboscis into the blood of the human subject, the disease is again induced;

thus is furnished an instance of a supposed non-transmissible disease affording an example of a typically transmissible one.

In the article 'Bacteria' it is stated that the infective agent in disease is almost invariably a lowly developed micro-organism, a vegetable or an animal blood-parasite. For the present we may leave out of account the larger animal parasites, which, however, in so far as they multiply and give rise to certain lesions, may be looked upon as infective agents. Some of these disease-producing bacteria grow readily outside the body, flourish at a temperature considerably below that of the human blood, subsist on nutrient media outside the body, and retain their vitality under conditions varying in some cases widely from those met with in the animal organism. Such bacteria, after making their way from the patient, may remain alive for considerable periods lying in wait ready to invade another patient and so set up an attack of the disease with which they are causally associated. On the other hand certain disease-producing organisms are endowed merely with the power of existing and multiplying in the fluids and tissues of the living body. They can scarcely exist at any other than the blood-temperature, and may be so constituted that they are either unable to obtain nutriment from dead tissues, or are rapidly killed off by other organisms with which they have to compete. Here the *materies morbi* must be passed on directly from patient to patient if it is to remain alive and active. Once this process is set a-going the infective organism appears to become more and more distinctly parasitic, and so more and more capable of invading the higher organism, of multiplying therein, and of setting up the special fermentative and disease-producing processes with which they are associated. An organism that can live outside the body may of course give rise to a transmissible disease either directly or indirectly, the *materies morbi* remaining outside—sometimes for very considerable periods—but where this disease-producing organism is strictly parasitic and cannot live outside the body, indirect transmissibility, though not unknown, is comparatively rare. The more saprophytic a disease-producing organism is, that is, the more it is able to live outside the body, the more important becomes indirect transmission; while in the case of the strictly parasitic organisms, indirect transmissibility plays a comparatively unimportant part. The facultative saprophytes (those bacteria that can live outside the body) which produce disease vary enormously as regards resistance to external agencies, a variation that may be noticed even in organisms of the same species. For example, the *Bacillus anthracis*, when placed under specially favourable conditions, multiplies very rapidly. When inoculated into the tissues of an animal and thence into the blood, it undergoes rapid multiplication by a process of fission, and in a very short time invades the whole of the fluids of the body. It will be found, however, that in this stage the bacillus is very easily killed. If a drop of the blood of the affected animal be transferred to another animal, the disease is reproduced with great certainty and rapidity. If, however, the animal after it succumbs be buried at once, these bacteria die out and are no longer a source of danger, since the bacteria kept within the body do not develop spores and are comparatively easily killed. If, however, the blood from an animal affected with

anthrax be allowed to escape and come in contact with the air, especially on a porous surface kept fairly moist, as on the surface of damp ground, the contained bacilli rapidly undergo such change that it is with the utmost difficulty they are destroyed, for resisting spores are formed which may be dried, heated, and even treated with certain antiseptics with impunity, and still remain alive, ready to develop into active bacilli as soon as the conditions for their growth again become favourable. They are not killed when they are buried, and, for long periods, remain capable of setting up an infection. In the one case the transmissibility must be direct, in the other case it must necessarily be indirect. The old term of 'contagion' then may be discarded with advantage.

One of the essential features of an infective agent is that it must be capable of multiplication in the fluids and tissues of the animal body, and the more this property is developed, the more dangerous becomes the organism as an infective agent. It is evident that in infection we are dealing with a process of insemination, but all the seed that is sown does not necessarily bear fruit; several factors must be favourable before a disease can be set up even by a disease-producing organism. Among these factors may be considered the following:—*The number of organisms introduced.* It has been found, for example, that a certain number of even virulent anthrax-bacilli may be introduced directly into the circulation of an animal without setting up any specific infective disease, the bactericidal power of healthy blood appearing to be quite sufficient to destroy a small number of bacteria, with the result that no infection takes place. *The virulence of the organism* also plays a part in determining this infection; a much smaller number of a virulent organism being sufficient to bring about what only a much larger number of less virulent organisms can achieve. In the case of the poison-producing organisms, such as the bacilli of tetanus and diphtheria, the poison plays a most important part in determining whether infection takes place or not. The micro-organisms introduced alone may be able to make no headway in the tissues; they are unable to multiply, and are readily destroyed, and no infective process results. If, however, along with the micro-organisms a certain amount of their specific toxin be introduced, the tissues or the fluids of the body with their bactericidal powers may be so reduced or interfered with that they are unable to repel the invasion of the bacteria, and an infective process is set up. *Impaired tissue-vitality*, brought about through whatever agency—want of nutrition, impaired excretion, impaired vitality of any kind through mechanical injury, cold, heat, toxins, or chemical irritants, whether general or local—is also of importance as predisposing to infective diseases from the fact that fewer and less virulent organisms can make good their position in the tissues under these conditions than when the vitality of the tissues is unimpaired (see BACTERIA, p. 133). In this connection must be considered the effect of the invasion of the tissues by two or more organisms. *Mixed infections* are in most instances far more serious in their results than are simple infections, and a disease, which under ordinary circumstances might run a comparatively mild course, may in the presence of the effects of a superadded organism become most dangerous. For example, in 'pre-antitoxin days' it was recognised

that if diphtheria was superadded to a case of scarlet fever, of however mild a type, it very frequently ended fatally, the mortality among such cases being very high indeed. That this was due, in great measure, to the mixed infection is evident from the fact that the mortality among such cases was very much higher than the mortality among cases either of simple scarlet fever or of diphtheria in the same epidemic. We have further evidence of the importance of this cumulative action in the success of the treatment of such cases with antitoxic serum, in which the diphtheria-factor is practically eliminated, the anti-toxin neutralising the diphtheria-toxin. As such cases come under observation at an early period, the treatment can be thoroughly carried out, and the mortality falls to a fraction of what it was in the 'pre-antitoxin period.' This is not an isolated instance. When the *Streptococcus erysipellatis* of a comparatively mild type is inoculated along with the *Bacillus prodigiosus*, which by itself is almost innocuous, a most virulent type of erysipelas may be induced; again, it is a matter of common observation that the *Bacillus tetani*, when reinforced by certain innocuous chemical substances or by certain non-pathogenetic organisms, may set up a most virulent form of tetanus.

Of other predispositions to infection may be mentioned *inflammatory conditions* which appear to act in a very interesting fashion. During an epidemic of cholera, only those patients contract the disease who first suffer from some slight disturbance of the alimentary tract; even when the cholera-bacilli are present in the lower part of the alimentary canal, there may be no attack of cholera unless some inflammation with its accompanying serous exudation be set up. Hueppe and Wood have pointed out that, for the production of considerable quantities of the cholera-poison, the bacillus requires a certain proportion of what may be termed crude albuminous material. This may be supplied in the form of egg-albumen or in the serous constituents of the blood. How does this bear on cholera? The cholera-bacillus in the alimentary canal may remain latent, as it were, for a considerable period, producing a comparatively small amount of poison; it has been so weakened by its passage through the stomach, and the medium on which it can grow is so little favourable, that the toxin is formed in insufficient quantities to do the patient much harm. When, however, from any cause there is irritation of the gastro-intestinal tract, interference with the secretion of acid by the stomach, or the pouring out of serous fluid as the result of an inflammatory process, the conditions immediately favour the production of toxin, and an attack of cholera is the result. There is good reason to assume that in the case both of the typhoid-bacillus and of the cholera-bacillus, the more virulent it is the more nearly it approaches the obligate parasitic condition, i.e. although it grows readily and produces a large quantity of poison within the body, it is much more easily killed outside the body; while, on the other hand, the more saprophytic in character it becomes, that is, the more it resists external influences and the more it becomes modified so that it can lead an existence outside the body, the less virulent are its characters as a parasite and an infective agent. The diphtheria-bacillus also may remain inactive for very considerable periods in the healthy throat; it is only when, as the result of inflammation, there

is an exudation of serous fluid that it is capable of multiplying rapidly, of producing large quantities of toxin from the crude albumen, and so of setting up a characteristic diphtherial infection and intoxication.

This question of predisposition to infection crops up in connection with almost every one of the infective diseases. The tissue-parasites, such as the bacilli of tuberculosis and leprosy, and the streptococci and staphylococci appear to be controlled by the tissues, the general nutrition rather than any special tissue-insusceptibility apparently being the most important factor. In the case of the exanthemata, however, this general nutrition, though, no doubt, playing a part, is comparatively unimportant as compared with special immunity or special predisposition. See IMMUNITY.

It must be borne in mind that even after bacteria—taking them as an example—have gained a footing in the tissues, a considerable period may ensue before they have multiplied sufficiently and have produced their toxin in sufficient quantities to produce any local or constitutional effects in the patient (see INCUBATION). It must be remembered that disease-producing organisms within certain limits always breed true, though they may vary greatly in virulence, in powers of growth, and in power of producing toxins; on the other hand, they may give rise to somewhat different results according to the tissues in which they grow and the paths by which they enter the body. As an example of this may be taken the different forms of tuberculosis, all of them produced by the tubercle-bacillus, but varying enormously in their course and results. In one patient the tubercle-bacillus by its presence may give rise to the formation, first, of comparatively normal granulation-tissue, this gradually developing into fibrous tissue, as in chronic fibroid phthisis; the bacilli in this instance appearing to invade the tissues by the lymphatics. In another case bacilli in exactly the same position may give rise to granulation-tissue much more rapid and luxuriant in its growth, ultimately undergoing caseous degeneration. Again, the tubercular processes resulting from the invasion of an epithelial surface, as in tubercular catarrhal pneumonia, may be essentially different, as regards naked-eye appearances, from chronic fibroid tuberculosis; and when the tubercle-bacilli make their way into the blood-vascular system, miliary tubercles scattered through the whole of the organs of the body—tubercles, which at first sight appear to have little in common with the large caseous tubercular masses found in the lung, liver, or lymphatic glands—result. In certain forms of infection the multiplication of the *materies morbi* takes place not so much in the tissues as in certain cavities, ducts, or channels, or in superficial wounds. It is only when the bacteria in these positions can produce toxins that they can play any important part as infective agents. Indeed it would perhaps be better to speak of them as toxin-producing agents. This has already been referred to in connection with cholera and diphtheria, and the same statements are true of the tetanus-bacillus. The diphtheria-bacillus may, in very severe cases, make its way from the lesion of the throat into distant parts of the body, but in the case of cholera the bacillus appears up to the time of death of the patient to remain in or near the alimentary tract or, in the case of tetanus, in the superficial wound.

Even disease-producing organisms may, as we

have seen in the case of the cholera-bacillus, lead a saprophytic existence in the cavities of the body. The pneumococcus is often found in the secretions of the buccal and respiratory mucous membranes of patients who are suffering from none of the toxic or infective effects usually associated with this organism as a parasite, while it is well known that certain of the pus-producing organisms are regularly present in the tonsils and in the appendages of the skin.

The alimentary canal being a cavity in communication with the outer world may contain in one or other of its divisions almost any organisms usually found outside the body. They may remain simply as saprophytic organisms, though, by the aid of their toxins, or through the weakening of the protective epithelium, they may gradually make their way into the tissues, there becoming parasitic and infective in the true sense of the word; in this they are invariably aided by the pouring out of serous fluids in which they become more and more parasitic and are enabled to produce their specific poisons.

Infection, therefore, may commence with intoxication, and it also results in intoxication. An infection may be local, in which case, as in tetanus and diphtheria, we have the infective agent multiplying at the point of invasion of the organism and sending out toxins to various parts of the body, giving rise to special changes in the central nerve-cells as in tetanus, or in the muscles and nerves as in diphtheria; while in both cases the poison, if present in large quantities, may act directly upon the secretory cells of the liver, kidney, &c. In other cases the infective agent spreads along the lymphatics as in erysipelas, the streptococcus found in this disease gradually passing from point to point, being rapidly destroyed, however, by the tissues which react to the stimulation set up by the advancing micro-organism. Or, again, the infective material may be carried to distant parts of the body by the blood- or lymph-streams as in abscess-formation, the infective agent becoming impacted in a capillary, and setting up a metastatic abscess.

As the local results of infection we may have inflammation, as seen in the dilatation of the blood-vessels, the accumulation of leucocytes, and proliferation of the connective-tissue cells, or, if the process be more acute, fibrinous exudation or death of the tissue resulting from the action of the poisonous substances plus the altered circulatory and mechanical conditions; in abscess-formation peptonising enzymes aid materially in bringing about the destruction of the tissues.

In addition to these special changes are certain general changes, some already mentioned, which result from the action of bacterial poisons, and appear to be due to the action of some substance, common to bacteria, described by Buchner, Centanni, and others as a protein, and found, for example, in pyogenic bacteria, and in the bacilli of anthrax, typhoid fever, and tetanus. When injected it is capable of setting up fever, diarrhoea, leucocytosis, and nutritive, respiratory, and vascular changes. These general changes then are induced by a non-specific bacterial substance similar in certain respects to those initiating local changes.

An infective disease may be endemic, in which case it may be taken for granted that the infective organism is distinctly saprophytic. In such cases the conditions must be exceedingly favourable to the continued existence of the bacillus outside the human or animal body; but in most instances it

appears to be essential that there should be a host to whom, now and again, the parasite may resort in order that it may retain its parasitic habit. There cannot, of course, be any evidence to show that there is any persistence of a disease-producing organism in a purely saprophytic form, without its coming at some time or other to inhabit a higher animal organism.

In the case of epidemics it may be assumed that transmissibility is practically direct from individual to individual, especially where no special predisposition appears to be necessary. Epidemics may result from the rapid distribution of the *materies morbi* from a centre in which it is endemic. This is especially the case in water-borne diseases and when, through starvation or fatigue, large bodies of people, as in times of warfare, are peculiarly susceptible to infection; or, finally, there may be epidemics of diseases from cases of which the virus is readily transmitted indirectly, especially where hygienic and nutritive conditions are bad, as in an outbreak of plague.

In order to deal efficiently with disease a knowledge of the method of infection and the nature of the disease-producing organism must be obtained at the very outset. In glanders, tuberculosis, diphtheria, plague, and the pyogenic affections, as well possibly as measles, variola, scarlatina, and leprosy, the exciting organisms can probably live for a time outside the body, that is, they may be saprophytic organisms. Here then it is necessary to prevent not only direct infection, but also the possibility of these organisms returning to their saprophytic existence. In the case of small-pox and scarlet fever, this can be fairly readily carried out, as in these direct transmission plays a much more important part than indirect. If the patients are kept isolated during the period when the infective organisms are given off, and if disinfection is carefully carried out, there is little danger of the infective agent being passed on to other patients. In tuberculosis, diphtheria, plague, and, to a less degree, glanders, something more than mere isolation is necessary. Building up of the tissues, air, light, and improvement of the general hygienic conditions, all play a great part in preventing infection; and this is especially the case in diseases in which predisposition is an important factor.

Those diseases which result from the invasion of such facultative parasites as the bacilli of typhoid fever, cholera, anthrax, &c., are not to be stamped out by isolation merely. The supply of the infective agent must be cut off, and this must be done while the organism can be readily destroyed, that is, immediately it comes from the patient. But, beyond this, the primary or common source of infection should be found, and measures taken to eradicate it.

As regards those fermentation-processes set up in the alimentary canal—say, by saprophytic organisms which have the power of producing irritant or toxic substances, but which have no power of invading the tissues—little need here be said, except to point out that under certain conditions these may prepare the ground for the action of such disease-producing germs as the cholera- or typhoid-bacillus.

It has been proved experimentally that the channels by which the infective agents enter the system vary very considerably in different cases, and that an organism which inhaled might give rise to a very severe attack of a disease would, as in the case of

small-pox, when introduced subcutaneously set up a comparatively mild attack. There are numerous similar infective agents. For example, the bacillus of Quarter-III, when injected into the subcutaneous tissue, gives rise to an attack of the disease, while, injected into the blood-vessels, it produces little or no effect. Further, a much larger dose of *Bacillus pyocyaneus* can be given subcutaneously than either intra-peritoneally or intra-venously. The typhoid-bacillus, on the other hand, is better borne when injected intra-venously than intra-peritoneally, while an animal will bear an intra-peritoneal injection of a larger quantity of the diphtheria-bacillus than it will bear subcutaneously.

As regards the protective action of the gastric juice, it may be mentioned that the acid contained therein affords very efficient protection against the invasion of the lower regions of the alimentary tract by the tubercle-bacillus or the cholera-bacillus. Tuberculosis of the intestinal tract, where the gastric secretion remains normal, appears to be almost unknown; while Koch found that it was necessary to neutralise this acid in the stomach of the guinea-pig before there was any possibility of the cholera-bacillus passing through the stomach into the intestinal canal. Even when it passed this portal, it met another of the protective agencies, the peristaltic action of the intestine, which, keeping the contents of the intestine with the contained cholera-bacilli constantly in motion, prevented the development of the toxins, with the result that no cholera was produced. There was no multiplication of the cholera-bacillus unless this movement was paralysed by the exhibition of morphia.

GERMAN SIMS WOODHEAD.

INFILTRATION (*in*, into; and *filtrō*, I strain through felt).—See DEGENERATION; and CONCRETIONS.

INFLAMMATION (*inflammō*, I set on fire).—SYNON.: Fr. *Inflammation*; Ger. *Entzündung*.

DEFINITION.—Very numerous definitions have been given of inflammation. The most generally received has been that attributed to Celsus, which gives the four marks of inflammation as *rubor, tumor, calor, dolor*; but this appears to have been really due to Erasistratus, who, according to Galen, first gave precision to the conception of simple burning, as understood by the older Greek physicians, and applied the name *φλεγμονή* (previously synonymous with *φλόγωσις*) to a swelling, which had also the characters of heat, pain, throbbing, and resistance. The definition was thus based upon the notion of *swelling*, and would hardly have taken this particular form had it been derived from superficial inflammations. Although the four 'cardinal' signs may still be recognised in what we call inflammation, this definition is now inadequate. Many attempts have been made to arrive at one which shall be more complete; and at the present day very various definitions are given by different pathologists.

The most popular definition is based upon the cause, viz. that inflammation is a series of changes produced in a part by injury which may be mechanical, physical, chemical, or due to living organisms; provided the damage produced does not entirely destroy the vitality of the part. This is a definition of the cause rather than of the process, and is logically defective since it excludes certain consequences of injury such as hemorrhage and the results of simple section of

vessels, nerves, &c. Some (as Adami) limit the definition to the 'local attempt at repair of injury,' which others object to as involving the teleological idea of purpose or intention. Others would include only injuries produced by micro-organisms which are the chief causes of the diseases called inflammations in the human body. Some exclude the process of repair from inflammation proper; others (as Ziegler) would define the process as *local tissue-degeneration* produced by injury, combined with *exudation* and followed sooner or later by *regeneration*. It would be really more correct to speak of inflammations than of inflammation; since the changes produced by different specific injuries differ so much that it is difficult to define any one form which can be called simple inflammation. In the face of these conflicting definitions, Thoma (with whom the present writer agrees) has proposed to drop the term 'inflammation' altogether, as involving merely a traditional conception, and to speak only of injury and the reaction produced by it; the process of repair being considered separately. As, however, the term 'inflammation' is certainly likely to be still used, it cannot be at once dropped, but we may understand that it means nothing more than certain consequences of injury. These consequences appear to be: (1) damage of cells or tissues; (2) a defensive reaction on the part of the organism which has the effect of removing the injurious agent, or of neutralising wholly or completely its effects; and (3) the process of repair which may or may not be regarded as actually a part of the same process. These three factors will have to be considered separately.

1. *Damage or injury.*—Admitting that an injury of some kind is always the starting-point of the processes called inflammation, we must regard the other changes as secondary to this. In all animals with a complete blood-circulation, injury to any vascular part sets up disturbances of the nervous and vascular mechanism, resulting in hyperæmia, which in slight injuries may be the only visible effect. In severer injuries they always accompany the other changes, and hence are an integral part of the process. Bearing this in mind, a gradation may be traced in the effects of injury. A very slight injury to the skin, for instance, by friction, heat, or a chemical irritant, produces transitory hyperæmia; a more severe or more lasting injury sets up inflammation (blister or eczema); one still more intense, necrosis or sloughing. The same gradation may be seen in the after-effects of cold, which, according to its duration or intensity, may lead to mere heat and throbbing, or to inflammation (chilblains or mild frostbite), or to actual gangrene. Even in apparently spontaneous inflammations a cause of injury may always be traced, such, for instance, as a diffusible virus, or the presence of micro-organisms and their products. Again, disturbances of circulation and innervation, as in the secondary inflammations of circulatory and nervous diseases, or a mere lowered state of nutrition, as in various chronic cachexias, are regarded as causes of inflammation; but in such cases there is generally a combination of injuries, the presence of some noxious substance coinciding with nervous, vascular, or nutritional disturbance. Frequently it appears that the lowered state of nutrition thus induced permits micro-organisms to exert their pathogenic effects, which the resistance of healthy tissues would otherwise inhibit.

Damage of cells or tissues shows various degrees up to and including total necrosis. In cells the chief signs are cloudiness, or cloudy swelling of the protoplasm; and indistinctness of the nuclei which are imperfectly coloured by staining reagents.

Fibres of connective-tissue swell up and lose their elasticity; muscle-fibres lose their striation and the nuclei become indistinct; nerve-fibres pass into fatty degeneration. These changes were called by Virchow 'parenchymatous inflammation,' but are not now regarded as constituting inflammation unless accompanied by other changes.

2. *The defensive reaction* includes (at least in the higher animals) hyperæmia and exudation. The exudate not only acts mechanically, but by its chemical constituents has an inhibitory action on micro-organisms; and it also assists nutrition in the process of repair. Some, with Metschnikoff, attribute a special defensive function to certain leucocytes. The new formation of connective tissue is also a defensive reaction, forming a barrier against the penetration of foreign substances into the organism, or surrounding them so as to render them inert.

3. The process of repair consists in the new formation of tissue-elements to replace those destroyed. It is seen in epithelial, muscular, and nervous elements, but most conspicuously in connective-tissue. The newly formed connective-tissue not only constitutes a defensive barrier, but replaces other tissues which have less power of repair, thus forming a scar.

Since animals are so constructed that injuries short of death always call forth some attempt at repair, we find that along with damage there is always some sign of restoration. The combination of these two factors constitutes inflammation, distinguishing it from necrosis on the one hand, and simple hyperplasia on the other. Accordingly a part of the inflammatory process may be regarded as conservative, tending to compensate the disturbance produced by injury. Hence inflammation often accompanies repair, but can hardly be considered as a necessary part of the latter process. The truth appears to be that in 'clean' or aseptic wounds, however extensive, there is little damage to the tissues. Damage is caused by the secondary injuries resulting from the entrance of bacteria or irritating substances, and when this occurs there is inflammation. In this case the delayed healing which follows cannot be attributed to the original injury, nor, strictly speaking, to inflammation, but to the secondary complications which produce the inflammation, and which this process actually tends to compensate and remove.

These secondary processes may be seen in operation simultaneously in any inflamed—that is injured—part; but the damage to the tissue is evidently the primary change, which calls forth the other processes. In studying the effects of injury in their simplest form, that is, in the lower animals without a blood-circulation, it is evidently right to begin with the tissue-changes; but since in the higher animals the vascular changes are indissolubly associated with these, and are the most conspicuous, it will be more convenient to begin with them. We shall, therefore, consider separately: (1) the vascular processes—hyperæmia and exudation; (2) the changes in the tissues.

I. DIRECT OBSERVATION OF THE VASCULAR PROCESSES IN INFLAMMATION.—When the mesen-

tery or tongue of a frog is drawn out and placed under the microscope, the contact of the air soon determines inflammation. The earliest change seen in the vessels of a part thus exposed is dilatation, first of the arteries, then of the veins, the capillaries being little affected. The dilatation of the vessels is accompanied at first by acceleration of the blood-stream, most noticeable in the arteries; but the acceleration does not last more than half an hour or an hour, and it then gives place to retardation, which continues as long as the inflammation lasts. The 'primary acceleration' is, however, sometimes absent or too short in its duration to be noticeable. So far, the process is doubtless the same as in active hyperæmia produced by local irritation. Whether the first dilatation is due to direct paralysis of the muscular walls of the arteries, or to a reflex action passing through the spinal cord, or to an inhibitory action passing through nerve-ganglia in the arterial walls, is uncertain. There is, however, no necessary connection with the spinal cord, since dilatation may take place when the part is disconnected from the great nerve-centres.

From this point begin the phenomena peculiar to inflammation. The dilatation of arteries may go on increasing for ten or twelve hours, till they have twice their original diameter, and pulsation becomes very prominent in them. The capillaries look as if gorged with corpuscles, forming a quasi-solid mass. The blood-current in all the vessels becomes slower and slower, till it is almost stagnant. This condition has been called *stasis*; but it is better to reserve this name for an absolute stagnation, which is no necessary part of inflammation, but is produced in experimental inflammations by local causes, chiefly, probably, by drying up of the tissues. In true inflammation the amount of blood passing through the part is always greatly increased, as may be seen by the fuller current in the veins leading from it. At the same time certain peculiarities are observed in the behaviour of the red corpuscles and leucocytes in the veins. In ordinary conditions of the circulation, the central part only of the vein (as of the artery) is occupied by the corpuscles, which move on mingled together. But during retardation the corpuscles, especially the leucocytes, spread over the marginal portion of the vein usually free from them, and the leucocytes begin to drag along the walls of the vein, as if adherent, till at length they form a layer lining the wall of the vessel, while the red corpuscles are carried on by the current. In the capillaries, this marginal layer is never perfectly established, though leucocytes may be seen momentarily adhering to, or moving slowly along, the walls. In the arteries, no such process is observed, except (according to Cohnheim) for a moment during the diastole of the pulse. This *marginal position* of corpuscles is a purely physical phenomenon, depending upon retarded motion. It has even been imitated experimentally in the case of particles moving in a fluid where the particles have a lower specific gravity than the fluid (Hamilton). When this *marginal position* of leucocytes is established, begins the process which, observed long ago by Waller, and less clearly though earlier by William Addison, was re-observed and brought into notice by Cohnheim. In the words of the last-named observer: 'On the outer contour of the wall of a vessel, usually a vein, in which the marginal layer of leucocytes is well

developed, sometimes first in a capillary, is seen a small projection which enlarges in length and breadth, and becomes a roundish colourless lump. This again enlarges, puts out new pointed projections, and gradually withdraws itself from the wall of the vessel, till it is attached to it only by a long narrow stem. Finally this attachment also is broken, and we see a colourless contractile body with one long process and several shorter, with one or several nuclei—in fact, a *leucocyte*.⁷ The same process is going on meanwhile at other points of the veins and capillaries, till at length, either quickly or slowly, the outer surface of all the visible veins becomes covered with several rows of leucocytes, while their interior shows the same appearance as before. That the leucocytes seen outside were formerly inside the veins, having simply passed through the walls, admits of no reasonable doubt, though it is often difficult for the eye to seize the precise moment of passage. In the arteries nothing of the kind is seen. In the capillaries the emigration of leucocytes is very evident, and accompanied by the passage of red corpuscles also through the walls, which does not take place in the veins proper. It is also clear that the passage of corpuscles takes place at the lines of junction of the cells constituting the capillary wall. It has been shown that the blood-plaques or platelets emigrate from the vessels under the same circumstances.

Accompanying the extravasation of the blood-corpuscles there is always a copious exudation of fluid, which goes far beyond physiological limits. The fluid also differs from the ordinary physiological transudation and more resembles blood-plasma. Aided by this and by their own spontaneous movements, the leucocytes are carried far and wide into the tissues, till the whole field, that is, the whole mesentery, is so crowded with them that nothing else can be seen. The red corpuscles, on the other hand, remain more closely in the neighbourhood of the vessels. When the exudation, carrying with it the corpuscles, and containing, as it does, coagulable material, reaches a surface, it forms the layer of inflammatory lymph or 'false membrane,' seen in inflammations of serous surfaces. The tissue, at the same time, becomes more or less infiltrated with lymphoid corpuscles, producing the condition known as 'small-celled infiltration.'

Cause of retardation and cell-emigration.—The processes just described mark inflammation off sharply from simple hyperæmia. There is little doubt that the essential factor in their production is a change in the constitution of the vascular wall, though it is possible that this may be connected with a change in the tissues outside, especially with a loss of elasticity, which may be traced in all injured tissues—as may be seen, for instance, in the production of a 'wheal' by a blow on the skin. The same change, while it retards the passage of blood, makes the vascular wall permeable to the corpuscles, and favours exudation. What the change is we cannot say, but it seems probable that it is the same as that which the walls of vessels undergo when inadequately nourished. Two classes of experiments throw light on this point. It has been found by Ryneck that fluids other than blood, such as milk, pass with greater difficulty than usual through the vessels of an irritated part; and that stagnation can be produced in the vessels of a frog, which is kept alive by the circulation of salt-solution instead of blood in its vessels. Cohnheim has

also shown that a state of the vascular walls similar to that which may be presumed to exist in inflammation may be produced by shutting off the blood from the vessels for a certain time. He put a ligature round the tongue of a frog, and observed the vessels after the ligature was cut. If the blood had been excluded for twelve to twenty-four hours only, the vessels on the return of the blood passed into a condition of simple hyperæmia; but if longer, stagnation, marginal position of leucocytes, and extravasation of corpuscles were observed, and these phenomena were more marked the longer the ligature had remained, provided it was not long enough entirely to destroy the vitality of the part. From these experiments we must conclude that the cause of the stagnation and its attendant phenomena is not in the blood or the cells, but in the walls of the vessels, and that the change in these is of the nature of degeneration.

2. CHANGES OF THE TISSUE-ELEMENTS.—*Tissue-changes in non-vascular parts.*—If the centre of a frog's cornea be touched with a solution of chloride of zinc, the nearest corneal corpuscles are destroyed. No naked-eye change follows, but in three days karyokinetic changes may be observed in the surrounding corpuscles. By this process repair is completed. If, however, the anterior corneal lamina be destroyed, or if a considerable area of the cornea be damaged, the cornea becomes turbid from the presence of large numbers of migratory leucocytes brought to the spot by the lymphatics. Some of these migrated cells may, perhaps, assist in forming the repair-tissue.

Tissue-changes in vascular parts.—In the omentum of mammalia, changes occur during inflammation in which unbiassed observation can see nothing else than cell-division, growth, and germination. There is indeed reason to believe that such appearances are found normally, as evidence merely of growth, but the inflammatory changes are distinguished from the normal by their greater rapidity and luxuriance. In fibrous connective tissue similar processes have long been observed, and, since attention was drawn to them by Virchow, have been regarded till lately as showing, in the clearest manner, that the fixed cells of the tissue germinate and produce new elements. This 'proliferation of connective tissue' is an obvious fact, but its importance is chiefly, if not entirely, in relation to tissue-formation, and not in the production of lymphoid or pus-cells, often ascribed to it. Around inflamed parts the connective tissue is often found infiltrated with lymphoid cells, the origin of which was formerly set down to proliferation, but which are chiefly leucocytes derived from the veins and capillaries of the inflamed part. The possibility, however, of the production of some lymphoid cells by proliferation of the fixed elements cannot be denied.

There is also reason to believe that the leucocytes emigrated from the vessels may further divide and 'proliferate.' Stricker and Klein have both observed actual cell-division take place under the microscope; so that some of the new cells may be regarded as the descendants of emigrated corpuscles. We may then compare the small or lymphoid cells of inflamed parts to the population of a colony, where most are emigrants, or the descendants of emigrants, but some few trace their descent from the aboriginal inhabitants.

Activity of the Corpuscles outside the Vessels—Phagocytosis.—The lymphoid corpuscles derived

from the blood-vessels show great activity and probably discharge important functions after they have left the vessels. They certainly bear a part in the mechanism of defence. One evident function which they perform is that of absorbing and removing injurious foreign particles from the seat of inflammation. Molecules of fat and pigment, and fragments of dead cells and tissues are taken up by them. When charged with fatty molecules they are the *granular corpuscles* once considered a special sign of inflammation. They also absorb bacteria, both dead and living. According to Metschnikoff there is a perpetual combat between the cells and the bacteria, and the name 'Phagocytes' has been given to those which have this power of absorption and destruction; the whole process being called 'Phagocytosis.' See PHAGOCYTOSIS.

Chemiotaxis.—The movements of these cells have been shown to be remarkably influenced by chemical substances dissolved in the serum which surrounds them, as well as by solid particles. Finely powdered copper and mercury attract the migratory cells, while gold and silver are inactive; but the most powerful attraction is exerted by chemical products derived from bacteria, or bacterial proteins. The protein from *B. pyocyaneus*, according to Büchner, acts even in a dilution of 1 in 3,000. Casein, gelatin, and certain albuminates act in the same way. This attractive power is called *positive chemiotaxis*. On the other hand ammonia, urea, leucin, and other substances are found to repel the wandering cells, exerting a *negative chemiotaxis*. Some of these facts explain the attraction of migratory corpuscles to an injured—i.e. inflamed—part, and also the action of these corpuscles in antagonising the effects of injury.

The importance of the processes of phagocytosis and chemiotaxis is that they indicate a direct action of the cells—chiefly blood- and lymph-corpuscles, but also some mesoblastic tissue-cells—against the injuries which constitute inflammation.

As it is chiefly bacteria and bacterial products which call forth these activities, we may conclude that their function is chiefly in relation to these organisms. The utility of these processes appears to be as a means of defence against the invasion of bacteria, and against the resulting infection. See IMMUNITY.

Changes in the tissue-elements.—These always show the combination of retrograde or degenerative with progressive or germinative changes, characteristic of inflammation, sometimes the one, sometimes the other, predominating, according to the severity of the injury and the nature of the tissue.

In *connective tissue* the retrograde changes consist in swelling and softening of the fibres, which may end in liquefaction, especially when there is suppuration. The progressive changes consist in proliferation and formation of new cells for the purpose of repair. Special histological methods generally permit us to distinguish these elements from migratory lymphoid corpuscles. Nuclear changes (karyokinesis) may often be traced in inflamed parts by proper methods, and are the most certain evidence of cell-proliferation, but are by no means peculiar to inflammation (see CELL). Tissue-repair begins with the formation of so-called epithelioid cells or fibroblasts, which sometimes enlarge into giant-cells. The nuclei of these cells become the nuclei of the new tissue-elements, the fibres of which are probably formed by splitting up of the protoplasm of the cells. Outgrowths from

the surrounding blood-vessels run into the new tissue and vascularise it. The whole process is thus one of continuous growth, quite independent of the migratory lymphoid cells, and of the hyperæmia and exudation, except in so far that the latter help by affording a more abundant supply of nourishment. The relation of the lymphoid cells to repair is thus very obscure.

Muscular tissue becomes granular and loses its striation under the influence of inflammation, and sometimes undergoes another peculiar form of degeneration. But at the same time the muscle-nuclei (unless the tissue be absolutely killed) show signs of growth and proliferation, by which in the end new fibres are produced and the tissue regenerated.

Nerve-fibres undergo rapid disintegration when inflamed; but the nuclei preserve their vitality, and are capable of producing new nerve-tubes, as is seen after section of nerves.

Ganglionic nervous tissue never shows any signs of regeneration after being inflamed, and is probably killed by comparatively slight and transient inflammations, though this tissue is very rarely thus affected.

Epithelium on mucous surfaces shows very characteristic changes. A large number of elements die and are shed off, so that the desquamation of epithelium is far more rapid than under normal conditions. Many cells show excessive mucous transformation and—in chronic inflammations—much fatty degeneration. There is also a copious formation of new epithelial cells, produced, as in normal conditions, apparently from the basement membrane.

Glandular epithelium, when inflamed, shows the characteristic change called granular degeneration or cloudy swelling (see DEGENERATION), which has been also called parenchymatous inflammation, and is evidence of the simplest kind of injury to the cells. Severe injuries cause fatty degeneration and breaking down, as seen in various kinds of poisoning. There is probably always a regeneration of gland-cells, but this is often traced with great difficulty.

The above are the tissue-changes usually met with in ordinary inflammations. When the inflammation takes the form of *suppuration*, destruction of tissue is far more complete, and repair is prevented, at least temporarily.

PRODUCTS AND RESULTS.—All inflammatory products result either from exudation or from new-growth. The exudative products are serum, mucus, and fibrin, the latter of which, in combination with leucocytes, forms the so-called 'inflammatory lymph.' New-growth takes place from the vessels in the form of vascular connective tissue, of which granulations are a special form. With regard to exudations, no clear line can be drawn, at any stage of the process, between serous and fibrinous exudation or inflammatory lymph. But the production of pus seems to require some special irritant or morbid factor.

Exudations.—Serous and mucous exudations can only be regarded as products of inflammation when excessive. The fluids formed in inflammations of serous cavities differ from those produced in passive exudations (or dropsies), in containing more fibrin and more albumen. But inflammatory exudations vary in this respect, and are sometimes scarcely to be distinguished from simple serous effusions. The

aids poured out on serous surfaces in acute inflammation always coagulate, and even in chronic cases are often shown to be capable of coagulation. On mucous surfaces, on the contrary, the exudation does not as a rule coagulate. That this is owing in some way to the action of the epithelium seems most probable, whether it is that filtration through epithelium alters the composition of the fluid, or whether the living epithelium prevents coagulation in the same way as the endothelium of the vessels prevents coagulation of the circulating blood. When, however, the epithelium is removed, a fibrinous layer may be produced on the exposed sub-mucous surface; and the same result seems to follow the application of very powerful irritants, as in croupous inflammations. Mucous exudations contain mucin, as well as serum-albumen, in variable proportions.

Fibrinous exudations, in coagulating, entangle whatever leucocytes may be either extruded with the exudation or present in the tissues. The properties of the coagulated mass differ according to the proportion of corpuscles. These differences do not necessarily show any corresponding differences in the composition of the blood, but depend upon the facility with which the corpuscles leave the vessels, and probably on the state of nutrition of the latter. The product called *inflammatory lymph* consists of coagulated fibrin entangling leucocytes, the two constituents being in varying proportions. The fibrin does not differ from that of blood-clot; and may therefore be formed in the same way by a reaction between the exuded constituents of blood. But it is not a constant product of inflammation, and hence has been thought to owe its production to local causes—that is, to reaction between the tissues and the exudation. Thus fibrin is formed on serous surfaces where one of the fibrin-constituents is normally found, and in fibrous tissue where there are similar chemical constituents; but, as stated above, not generally on inflamed mucous surfaces, or in epithelial structures. But since it is possible that in these cases the exudation becomes altered by filtration through the tissues, there is no reason to doubt that fibrin, or both its chemical constituents, may be exuded from the vessels. The inflammatory fibrin itself is never *organised*, but often becomes *replaced* by a vascular connective tissue which grows into it, and causes its absorption. This is the process formerly spoken of as ‘organisation of lymph.’

Pus.—Pus is inflammatory exudation in which the corpuscles greatly predominate, and the intermediate substance is liquid. It is thus difficult to draw a line between pus and some forms of inflammatory lymph, but the former does not contain fibrin, nor does it coagulate spontaneously. For the characters of pus and the exciting causes of suppuration reference may be made to the articles upon **ABSCESS** and **PYOGENIC ORGANISMS**.

Granulation-Tissue.—When a part has been destroyed by inflammation, the lost tissue is replaced by the preliminary formation of a peculiar structure, consisting of a highly vascular connective-tissue framework, containing an excessive number of leucocytes, and also epithelioid or formative cells, with occasional giant-cells. See **WOUNDS**, **Healing of**.

VARIETIES.—The most striking differences between different kinds of inflammation are those depending upon the differences of tissues, and of the situations in which it occurs.

1. *Catarrhal.*—On mucous membranes the exudation is mucous, does not coagulate, and contains only detached epithelial cells, with scattered leucocytes; the process tends to become chronic; but the effect on the body as a whole is less marked than in other forms. The term catarrhal inflammation is with less propriety transferred to inflammations of the skin, the lung, and some glandular organs, in which desquamation of epithelial cells is a prominent feature.

If catarrhal inflammation is very severe it becomes purulent, and the exudation consists chiefly of pus, little or no mucus being produced. This purulent catarrh is especially characteristic of specific inflammations of the mucous surfaces, such as virulent conjunctivitis or gonorrhoea.

2. *Croupous or fibrinous.*—Croupous inflammation is that form in which a coagulable exudation is formed upon a mucous surface. In *diphtheritic* inflammation there is, besides a membranous exudation, some necrosis of the mucous membrane. In these forms the tendency is to acute, not chronic, disease; and the general symptoms are strongly marked. The name ‘croupous’ has also been transferred to certain inflammations of the lung (‘croupous pneumonia’) and of the kidney, but (in the latter case especially) with doubtful propriety.

The *fibrinous* form may be regarded as the normal or usual form of inflammation of serous membranes and fibrous connective tissue.

On serous surfaces the lowest degree of inflammation is seen in a serous exudation, hardly to be distinguished from simple dropsy; but there is no clear line between this and a coagulable exudation, or fibrinous inflammation. This too, if still more severe, may become purulent; and, as we see in the pericardium or pleura, a purulent may succeed to a fibrinous inflammation. Finally, vascular connective tissue, forming adhesions, is generally produced. In areolar connective tissue, and in the interstitial tissue of various organs, the same stages may be distinguished, known as *inflammatory oedema*, which occurs near a focus of acute inflammation; *inflammatory hardening*, such as precedes the formation of an abscess; and, finally, either abscess itself or purulent infiltration—the two forms of suppuration in connective tissue.

3. *Parenchymatous.*—The name ‘parenchymatous inflammation’ has been given to the changes occurring in the special tissues of organs independent of their connective-tissue framework. In contradistinction to this, inflammation of the connective-tissue framework is termed *interstitial inflammation*.

4. *Phlegmonous.*—Phlegmonous inflammation is the same as *acute interstitial inflammation*, ending in the formation of abscess.

5. *Indurative.*—Indurative inflammation is that in which new connective tissue is produced in the interior of organs. This is *chronic interstitial inflammation*.

6. *Scrofulous.*—Scrofulous inflammation has been described as that type which occurs in cachectic persons, whose tissues are easily injured and heal slowly. But there can be little doubt that all scrofulous inflammations are really tubercular. *Strumous* is a word better forgotten, being synonymous with scrofulous, and liable to be misunderstood.

7. *Infective.*—Infective inflammations are those

produced by the passage into the blood of infective organisms, derived from some previously existing inflammation. Pyæmia and inflammations associated with the puerperal state are instances.

8. *Chronic*.—Most inflammations have at first a typical course, reaching their acme and then declining. If the decline is not followed by resolution they become chronic. Others, again, show from the first the character they all along maintain. Chronic inflammations are usually distinguished by the persistence of that condition of the vessels which permits exudation and cell-emigration, with less hyperæmia and general fever than in the acute form. On mucous surfaces the chronic form differs little from the acute, except in these two respects. In serous membranes chronic inflammation produces fibrous adhesions, with little or no liquid exudation. In the interstitial tissue of solid organs a large amount of new connective tissue is produced by chronic inflammation, which first compresses the special elements, causing them to waste, and then contracts in bulk, so that the organ becomes atrophied, and usually harder and more fibrous. This is the process called 'fibroid degeneration,' as in cirrhosis of the liver. 'Chronic parenchymatous inflammations' are simple degenerations, as seen in the kidney.

TERMINATIONS.—The most favourable termination of inflammation is what is called *resolution*, in which the vascular phenomena and tissue-changes decline together, and pass away without leaving any tangible material result. Even in the apparently most perfect cases of resolution, there is little doubt that products of exudation remain when the vascular changes have subsided, and are slowly removed by the lymphatics. Other so-called terminations are *necrosis*, or total death of the part; and partial destruction by suppurative or *ulceration*. But if any loss of substance occurs, the inflammatory process cannot be regarded as at an end till the loss is wholly or partially restored by newly formed connective tissue. Where there is no destruction of tissue, but only masses of liquid or solid exudation, the inflammation is not, strictly speaking, resolved till these are removed. Very frequently an acute passes into a chronic inflammation.

CONSEQUENCES.—1. *Local consequences*.—If an inflamed part does not simply return to its original state, *atrophy* is the most common consequence. *Hypertrophy* can hardly be said to occur in the part actually inflamed, though it may in adjoining parts, as we see in enlargement of bone from periostitis. False hypertrophy from new formation of connective tissue is common; but, as such tissue contracts, the final result is atrophy. The hardness of this tissue causes *induration* to be put down among the consequences of inflammation.

2. *General consequences*.—The effect of inflammation on the whole body is to produce the condition of *fever*, which is discussed in another part of this work (see FEVER). It is most probable that some fever-producing or *pyrogenic* substance passes into the blood from every inflamed part, and causes increased tissue-change, with consequent increased production of heat through the whole body; or else exerts a special action on the heat-centres. Several substances having a pyrogenic property have been isolated. They are either animal ferments (enzymes) or albumoses, produced by the action of bacteria on proteid substances. The degree in which local inflammations cause fever

varies, and does not appear to depend wholly on the mass or the intensity of the inflammation, though both these conditions are partly concerned. Acute inflammations produce more fever than chronic; those of connective-tissue more than those of mucous surfaces; and, most of all, those which end in suppuration. In infective inflammations the fever is generally high, but not to be attributed to the local inflammation, being a concurrent effect of the same cause—the infective poison. Besides general fever, the special conditions called *pyæmia* and *septicæmia* may be consequences of primary inflammation; but only when certain special causes are at work. See FEVER; and PYÆMIA.

ÆTIOLOGY.—All inflammations are caused by some injury—either mechanical, as by actual violence; or physical, as changes of temperature; or chemical, by powerfully acting substances, as acids, alkalis, and many more; or by micro-organisms. A most important secondary factor is the condition of the body, whether under- or over-nourished, or in some other way wrong; and this may probably be still more closely defined as the condition of the blood-vessels. Many parts of the body, as the skin and the stomach, are constantly exposed to injury, but do not become inflamed except from some internal cause; and, therefore, a change of nutrition may be the apparent or immediate cause. It is also clear that certain inflammations, as herpes zoster, are determined by disturbance of the nerves; and it is very probable that similar nervous disturbances cause other local inflammations. Besides these, there are certain specific causes, namely, infective or specific poisons, which, when introduced into the blood, produce local inflammations. Many local inflammations, external and internal, appear to arise spontaneously, neither irritation nor fault of nutrition being easily traced. But in these, as in others, it is probable that some infective cause is at work, or else that there is a gradual accumulation in the blood of some irritant substance, the effects of which are only seen when the nutrition of the part is lowered. Such, for instance, are the secondary inflammations which occur in chronic diseases (see BRIGHT'S DISEASE). It is also probable, and in some cases proved, that other inflammations which were at one time thought spontaneous, are really secondary, depending upon some previous local inflammation, even without what is called actual pyæmia. Thus the number of such apparently spontaneous inflammations is gradually lessening.

TREATMENT.—Doubtless the most satisfactory method of treating inflammation is by removing its cause. This cause being in so many cases the action of bacteria, antiseptic or bactericidal substances are often the most powerful agencies which can be used in treating inflammations, if they can be brought in contact with the pathogenic organisms. Many of the agents used in the treatment of local inflammations really act as bactericides. The treatment of gonorrhœa is a familiar instance. But these methods of treatment are *specific*, and cannot be brought under general rules; and are not here discussed. Treatment of inflammation proper is only called for when the inflammatory or defensive reaction is so much in excess as itself to constitute an injury. We shall divide this subject into the treatment of *directly accessible* (chiefly external) inflammations; and that of *indirectly accessible*

internal) inflammations. Treatment will also differ according as the inflammation is acute or chronic ; and also according to the constitution of the patient.

(a) *Directly accessible*.—Directly accessible inflammation in an early stage may be treated by local blood-letting, and by astringents. The benefit of local blood-letting in an early stage is undoubted, and it is probably due to its relieving the condition of stagnation, and permitting freer circulation of blood in the part. Of astringents the type is *cold*. When the vascular disturbance, that is, hyperæmia, is great, and the general fever high, cold, produced either by ice or evaporation, is generally the best treatment. In the case of mechanical injuries, for instance, it may be regarded as an ascertained fact that if any injured part be kept cold during the period of reaction, the inflammation is less severe. When the condition of inflammatory exudation is set up, the effect of cold is less marked ; and if a temporary benefit is produced, the condition after the application of cold is stopped may be as bad as ever, or perhaps worse. Cold is also a powerful nervous sedative, and reduces the nervous irritability of inflamed parts. An effect like that of cold is produced by solutions of certain *metallic salts*, especially those of lead, zinc, silver, and bismuth. These salts furnish the most certain and direct means of treating an inflammation in parts actually accessible to their action. Hence they are used in superficial inflammations of the mucous membranes, such as the digestive mucous membrane and the conjunctiva, and of the skin. These mineral (and also vegetable) astringents act more potently on the exudative processes of inflammation than on the vascular disturbance. Hence their activity is most valuable when that of cold ends ; and they have a striking effect on chronic inflammations which are unaffected by cold. Even *pressure* may be useful as an astringent, as we see in strapping a testicle or an inflamed joint.

In the treatment of even acute inflammations, the precisely opposite application, that of *heat*, is sometimes valuable. There are instances (such as the cure of a whitlow by plunging the finger into very hot water) where the sudden application of heat seems to cut an inflammation short. Probably this is only when the cause is some infective micro-organism. Short of this, heat doubtless increases the activity of most inflammatory processes. But heat combined with *moisture* is the type of an *emollient*, by which the substance of inflamed tissues is relaxed, the blood-vessels dilated, the sense of tension and nervous irritation removed ; and though exudative processes are probably encouraged, the *mechanical* condition of inflammatory stagnation is relieved, and resolution is thus hastened. When pus is forming, there is little doubt that heat and moisture (in the form of poultices and fomentations) hasten the process, and increase the amount of pus formed ; but since the increased production of pus is of no consequence, and it is more important to hasten the process, this may be the right treatment for suppuration. When pus is once formed, the same treatment is useful in guiding it in the direction in which it is least hurtful. Finally, it may be beneficial to apply heat and moisture superficially, to relieve deep-seated organs, by stimulating the vascular and lymphatic circulation through the skin. Thus, in applying poultices for pneumonia we do not make the lung or even the pleura hotter,

but relieve the overloaded blood-vessels and lymphatics.

Further, in treating all superficial inflammations we must guard against anything which increases the injury. Thus, in some skin-diseases, as herpes zoster, secondary inflammation is prevented by an artificial covering of collodion. The benefits of mechanical rest in treating injuries of the limbs need not be more than mentioned ; nor that of physiological rest, wherever it can be obtained, in threatened or existing inflammation of any active organ whatever—for example, the brain, the stomach, or the kidney.

Diet is also of great importance. There is little doubt that the intensity of all inflammations is lessened by greatly diminishing the food taken. In some acute inflammations, especially fevers, we may pursue a different system, with the view of saving the patient's strength ; but it is possible that in the reaction against the starving process, 'the feeding of fevers' may be in the present day sometimes carried too far.

In the treatment of *chronic inflammation* in accessible parts, the first aim will be to bring the tissues and vascular walls into a healthy state. Here we find that metallic and vegetable astringents are most useful. But it may, with the same object, be well to draw more blood into the part, in order that the vascular wall may be better nourished. This is effected by *stimulants*, which are of well-known efficacy in chronic inflammation. Some of these agents are the same as astringents, but in a more concentrated form—nitrate of silver, sulphate of copper, &c. ; others, like iodine and cantharides, are irritants. The local action of certain substances which may be called *aromatics* in healing some kinds of chronic inflammation is most remarkable. Thus, tar, either from wood or from coal, and similar bodies are used in chronic inflammations of the skin ; copaiba, cubebs, sandal-wood, &c., when excreted by the urine, act beneficially in chronic cystitis and urethritis. Benzoin, the tars, copaiba, tolu, and many other aromatic and resinous compounds, when excreted by the lungs, act in the same way on chronic bronchitis. The *rationale* of the action of these drugs is difficult to understand, but they are all oxidisable substances which undergo slow oxidation in the air, often accompanied by an ozonising action. They are also in varying degrees antiseptic or parasiticide. Again, it may happen that it is best to sweep the old tissue away, and allow new vessels to be formed, which will probably have healthier walls. This is effected by destructive *caustics*, as nitrate of silver, potassa fusa, chloride of zinc, or even the actual cautery.

(b) *Indirectly accessible*.—The treatment of indirectly accessible inflammations, or, what amounts to the same thing, the treatment by internal (general) methods even of directly accessible inflammations, is much less satisfactory than the local.

The first indication is to give the part actual rest, mechanical or physiological. The next is to consider if there is any way of reducing the intensity either of the local reaction, or of the fever. Of such means the chief are general blood-letting ; the general application of cold ; and certain particular drugs, such as mercurials, antimonials, purgatives, digitalis, aconite, quinine, and a number more. For the treatment of inflammations of special parts, the articles on these subjects must be consulted, as well as the articles on BLOOD, Abstraction of ;

COUNTER-IRRITANTS ; and HEAT, Therapeutic Use of.

The general treatment of chronic inflammation is based upon the principle that chronic inflammation is, in other words, *imperfect repair*. It is in cachectic persons, or persons with an inherited proclivity (perhaps not yet manifest) to cachectic diseases, that inflammations most tend to become chronic. Hence, the first rule is to improve the nutrition. Many patients with chronic inflammations get well at once when placed in good quarters, and on good food, provided that the digestive functions are first attended to. Next in importance come nutrient tonics, of which cod-liver oil is the chief. There are few chronic inflammations in which it does not do good. Iron is very often valuable ; and, if it fails or is contra-indicated, arsenic may be employed. In chronic inflammations of fibrous tissues, iodide of potassium has a real value, not easily explained.

Finally, a most important means of treating indirectly accessible inflammations must be mentioned, namely, that by *counter-irritants*, or setting up a rival inflammation. In order to relieve an inflammation, for instance, of the knee-joint, we produce a superficial inflammation of the skin. This is most used in chronic, but applies to some acute inflammations also. Various explanations have been given of the undoubted efficacy of this treatment. Some believe the action is transmitted through the nerves ; others that blood is drawn away ; others that the lymphatics are stimulated. The writer's belief is that in the most marked cases of benefit from counter-irritation there is a continuity of the tissue between the inflamed organ and the part where the counter-irritant is applied, and that the action may sometimes consist in drawing away blood ; but more generally the benefit results from setting up currents of plasma through the lymphatics and the connective-tissue spaces. It should be noted that in some inflammations where oedema is a marked feature (e.g. epididymitis), simple puncture has an unquestionable efficacy which may perhaps be explained in the same way. The substances used for counter-irritation are either vesicants or rubefacients, such as cantharides, ammonia, mustard, or iodine. Dry heat at different temperatures may produce the effect of either of these classes. When redness is produced on the skin, it does not follow that hyperæmia alone results. In fact, the desquamation often shows that a low form of inflammation has been established.

J. F. PAYNE.

INFLATION (*inflō*, I blow into).—A term applied, therapeutically, to the method of blowing air or gas into any hollow space. It is employed particularly in connection with the lungs in the process of artificial respiration (*see* ARTIFICIAL RESPIRATION). It is also used for the purpose of dilating the bowel in cases of obstruction, and for purposes of diagnosis in doubtful renal tumours. *See* INTES-TINAL OBSTRUCTION.

INFLUENZA.—SYNON. : Fr. *La Grippe* ; Ger. *Influenza*.

Influenza is an acute specific infectious disease characterised by fever, catarrhal affections of the respiratory and digestive systems, and nervous disorder of various types.

OCCURRENCE.—Numerous pandemics appear to

have occurred in the eighteenth century, and three at least in the nineteenth, beginning in 1837, 1847, and 1889 respectively. A pandemic is generally succeeded by epidemics, and by endemic prevalence in some areas. The disease is said to be endemic in China and in the eastern parts of the Russian Empire, and the pandemic of 1889 would seem to have had its origin in Central Asia (Bokhara).

ÆTIOLOGY.—The history of the pandemic of 1889 has proved that influenza is an infectious disorder disseminated by human intercourse. A specific bacillus was discovered by Pfeiffer in 1892 in the bronchial secretions, in the peribronchial tissues, and in the pleura. It has occasionally been found in the blood during the febrile stage, and, after death, in many organs, as, for instance, in the lungs in pneumonia, in the brain and meninges in meningitis and encephalo-meningitis, in the secretions of the tonsils in pharyngo-tonsillitis, in the accessory cavities of the nose, in the middle ear, &c.

Many of the symptoms and some of the sequelæ, including peripheral neuritis, are in all probability due to toxins produced by the bacillus in the body. The first symptoms of the disease usually develop from two to four days after exposure to infection, and the patient is capable of disseminating the disease throughout the whole course of his attack from the time of onset of the earliest symptoms, until convalescence has been sufficiently established to enable him to resume his ordinary avocations, it may be, even in mild cases, a week or ten days after the commencement of his illness. An attack of influenza does not confer any appreciable immunity, but it is a mistake to assert that one attack predisposes to another. The fact appears to be that the immunity is of short duration.

BACTERIOLOGY.—The *Bacillus influenzae* is a minute rod, 1.5 μ in length by 0.3 μ in breadth, and occurs principally in the sputum, arranged in pairs, or more rarely, in short chains of three or four elements. The bacillus does not stain readily with the usual dyes ; and is completely decolourised when treated by Gram's method. Prolonged staining (12 to 24 hours) in very dilute carbolie fuchsin gives the best results. The organism stains most deeply at the poles, and thereby often resembles a diplococcus. The B. influenzae is a non-motile, non-spore, obligate aërobie, and requires for its successful cultivation the presence of serum, blood, or solutions of hæmoglobin, in its nutrient media. It can only be grown at or near the body-temperature (30° C. to 43° C. ; Optimum, 37° C. ; Thermal Death-point, 60° C.). The duration of life of the bacillus in artificial cultures is limited to three or four days : dried cultures are dead within 24 hours. The B. influenzae is readily killed by desiccation or exposure to direct sunlight. The toxin of the bacillus has not yet been separated.

Cultural Characters.—Upon 'Blood-agar,' small discrete, transparent, raised colonies, resembling drops of water, appear at 18 to 24 hours ; they do not increase in size with age, although the centres sometimes become yellowish-brown in colour. In serum-broth small whitish flakes appear on the surface in 24 hours, but soon sink to the bottom of the tube, and form a flocculent deposit, leaving the supernatant fluid clear. The bacillus is pathogenic for the monkey, and probably for the rabbit also.

MORBID ANATOMY.—The morbid changes found after death from influenza are of a very varied character, and are in the main to be attributed to the

visceral lesions by which death has been brought about. Those due to the generalised disease are of a character common to all forms of acute infective disease—namely, parenchymatous degeneration of the liver, kidneys, and spleen, of the muscular substance of the heart, and of the minute vessels. The last-named may lead to capillary hæmorrhages into the viscera or nervous centres. The spleen may be much enlarged and almost diffuent. In the pneumonia of influenza the influenza-bacillus may be present alone or associated with the *Streptococcus pyogenes longus*, but the *Diplococcus pneumoniae* is present in the majority of cases. In the bronchial sputum these two microbes have also been found, while in the secretion of the nasal cavities the *Staphylococcus aureus* and *albus* and the *Bacillus capsulatus* of Friedländer have also been detected.

Morbidity and Mortality.—The proportion of a population which suffers from the disease at the beginning of a pandemic is high. In 1889–90 it was estimated that in St. Petersburg two-thirds, in Berlin one-third, in London nearly one-seventh of the population was attacked. Smeë estimated that in the years mentioned 8 per cent. of the total population of Europe suffered an attack of the disease, and a very large proportion of those who escaped then have suffered during epidemics which have occurred subsequently. The mortality attributed directly to influenza is low, and has been stated to range from 0·25 to 1 per cent. of persons attacked, but epidemic prevalence of influenza is always attended by a great rise in the general death-rate, which may be thrice the average. On analysis this rise is found to be due to an increase in the number of deaths attributed to bronchitis, bronchopneumonia, pneumonia, and other respiratory diseases, to diseases of the circulatory system, and to an unusual number of deaths among old people. It may be added here that influenza unquestionably tends to diminish the birth-rate. This influence may be in part due to its causing abortion.

SYMPTOMS.—The symptoms produced by influenza, the complications which may occur during its course, and the disorders by which it may be followed vary so greatly in individual cases that it is impossible to give any single picture of the disease. Three main types are usually recognised: the respiratory, the gastro-intestinal, and the nervous, to which ought, perhaps, to be added the febrile (Osler). This classification is not only convenient for purposes of description, but also corresponds to a natural character of the disease, as is shown by the occurrence of epidemics in which the majority of the cases are of one or other type. But it must not at the same time be recognised that this rule is far from being absolute, that cases of any type may occur during any epidemic, that the several types may be represented in the same household at the same time, and that the same patient may suffer from a combination of them, though this is not usual. It may, indeed, be said with truth that there is no organ or tissue of the body which may not suffer during an attack of influenza, though as a rule the brunt falls upon one system—respiratory, digestive, or nervous.

Respiratory Type.—The mildest form of this type, 'simple catarrhal fever' (Peacock), may be considered to be the most characteristic form of the disease; the symptoms to be described are seldom wanting at the beginning of an attack of any form of the disease, and those observed in other types

might, with much justice, be described as complications or sequelæ of the simple catarrhal type. This is true at least of first attacks; in subsequent attacks these early catarrhal symptoms may be little marked, though they are seldom together absent. The onset is usually sudden. The patient feels chilly, perhaps shivers; the surface is pale, and there is a general feeling of discomfort with, perhaps, headache, and ill-defined pains in the limbs. The mouth and nose are dry, and there is some oppression of breathing and a short dry cough. These symptoms are soon succeeded, generally in a few hours, by febrile reaction; the temperature rises to 101°, 102°, or even 104° F., the pulse is rapid and soft, the respiration is hurried, the skin is hot, dry, and flushed. The flush may amount to erythema, and be followed by desquamation. This is especially to be observed on the face, chest, and upper extremities. Within twenty-four hours, as a rule, the conjunctivæ become injected, the throat red and sore, and a thin watery discharge begins shortly to run from the eyes, and to be expelled by the cough which continues frequent; it often recurs in paroxysms which in children may suggest the onset of whooping cough. The respiration is more or less hurried, but physical examination of the chest reveals nothing beyond some harshness of respiration, with perhaps a few sibili or rhonchi on forced inspiration. The tongue has a white fur usually confined to the central parts, leaving the tip and edges red and irritable; there is thirst, almost complete loss of appetite, and, as a rule, constipation. The urine is scanty and high-coloured. The patient is restless and may be mildly delirious at night. During the day some patients are restless and excited, eager to do their usual work, if of an intellectual kind; others are listless and depressed; and all are very quickly fatigued. Epistaxis is not uncommon. After an interval of one or two days the temperature declines, the skin becomes moist, the conjunctival injection passes away, the secretion from the respiratory passages becomes opaque or muco-purulent, the tongue becomes clean, the appetite returns, and the patient is convalescent. The duration of the whole attack is on an average three to five days, but it may be extended to seven or ten days. The symptoms, then, of this form do not differ in any characteristic way from those of severe coryza or 'common cold,' and bacteriological investigations appear to confirm the opinion that during epidemic or endemic prevalence of influenza, some illnesses are attributed to it, which are in fact due to pyogenic infection (streptococci). As a rule, however, the frontal headache and the pain in the eyes and limbs are more marked in influenza than in coryza, and as a rule, also, the degree of physical and mental depression left after the fever has passed is much greater. Some patients are liable for weeks or months to profuse perspirations on slight exertion or at night, and others only very slowly regain their appetite and strength, so that the standard of general health remains 'below par' for a long period.

In more severe cases of this type symptoms and physical signs of bronchitis or pneumonia become prominent from an early stage, and the duration and course of the disease are determined by the progress of these complications. There is nothing characteristic about the bronchitis, unless it be that in some cases the expectoration is very copious, at first thin and clear, but containing later purulent

masses; Pfeiffer considers greenish-yellow nummular expectoration as characteristic, but it cannot be very common. In many cases, probably in a majority, the bronchitis is not specific, the catarrh produced by the specific infection opening the way to the ordinary infection of bronchitis. The severity of the bronchitis differs very greatly; there is seldom any danger except in old persons, or the subjects of chronic bronchitis. Pneumonia, of one or other form, is the most common of the serious complications of influenza, and is the main cause of the large mortality directly attributable to the disease. Very different opinions have been expressed as to the true nature of this complication. The fact appears to be that its pathology differs essentially in different cases. In some cases the inflammation of the lung is due to the specific infection; in others influenza is merely the determining cause of croupous or catarrhal pneumonia produced by the ordinary infective agents of those disorders. True specific influenzal pneumonia is lobular, and produced, as some think, by extension from the bronchi, but this sequence of events is not always to be discerned. It may, especially in the old, creep about from one part of the lung to another, or from one lung to the other, so that the physical signs vary in extent and situation almost from day to day. The duration of such cases is indefinite: apparent recovery may be followed again and again by relapse, and the patient's strength may thus be exhausted rather by the duration than by the extent or the severity of the pulmonary inflammation. Such cases may be seen also in young children; but in adolescents and adults the type is usually sthenic, and a whole lobe may be rapidly involved. Even in such cases the course is usually prolonged and irregular, and there is seldom any distinct crisis. The symptoms are not characteristic, the sputum is only rarely rusty or blood-stained, and usually becomes muco-purulent at an early stage. In favourable cases, after some ten or twelve days, the lung begins to resolve, the expectoration becomes more copious and purulent, and the patient is left in a depressed state to a long convalescence. In some cases the prominent symptoms are those of pleurisy, but as a rule in such cases they are succeeded by or combined with those of localised pneumonia, and much effusion into the pleural cavity is unusual. Lastly, influenza is very apt to become complicated by acute croupous pneumonia, the symptoms of the initial disorder running on into those of the latter. *See LUNGS, Inflammation of.*

Gastro-intestinal Type.—This type has been observed frequently during some of the epidemics which have occurred since 1889, but on the whole less often than the respiratory or the nervous. The onset is usually sudden, and to the symptoms observed in the milder cases of the respiratory type are added pain in the epigastrium, tenderness in various parts of the abdomen, nausea or vomiting, a coated tongue, and great depression, with often a dusky flushing of the face and chest. Epistaxis is not uncommon; enlargement of the spleen occurs in many cases, and is in proportion to the intensity of the fever. The tongue presents at first a uniform white fur, which often has a characteristic 'porcelain' appearance. This clears in patches on the second or third day, leaving the tongue red and irritable, or it is succeeded by a thin irregular brown coating accompanied by dryness. Mean-

while, diarrhoea has usually commenced. It is often accompanied by much painful colic, and the stools are loose and contain much mucus. The duration of such attacks is very various. In some cases the symptoms, with care and suitable diet, pass away in a few days; in others the temperature remains a degree or two above the normal, anorexia is complete, and thirst becomes troublesome. The patient complains much of abdominal pain, often of headache, and is sometimes mildly delirious at night, so that the condition simulates enteric fever. The conjunctivæ are injected, and along with the skin present a sub-icteric tint; in some epidemics well-marked jaundice has been common. In other cases, again, the fever subsides after two or three days, and appetite returns to some extent, but the digestive powers are much enfeebled, the stools continue loose and light-coloured, or if formed are pale and offensive, and of low specific gravity. This condition may continue for weeks, and the least indiscretion in diet may cause a relapse after apparent recovery. Cases are sometimes met with in which the most prominent symptoms at the onset are fever, bilious vomiting, constipation, and pain in the right iliac fossa, so that the case presents a great resemblance to appendicitis. It is, indeed, possible that the appendix is actually involved, and some would explain the increased frequency of appendicitis at the present time by the theory that it is a complication or sequela of influenza.

Nervous Type.—This type was exceedingly common during the last pandemic, and is frequently encountered in the epidemics which have succeeded it. Individual cases vary very much in severity, but in an average example the patient after a slight chill is seized with pain in the eyeballs, frontal headache, and pains in the back and limbs; the backache is in many cases very severe, and has been compared by women who have borne children to that experienced during childbirth. The temperature rises rapidly, reaching its maximum, in a large proportion of cases, within twenty-four hours; the rise is generally limited to 2° or 3° , but temperatures of 104° F., and even higher, have been noted. As the temperature rises the pulse becomes more frequent. It is soft, often feeble, and some cyanosis is not uncommon during the febrile period. As this passes away various disturbances of the cardiac rhythm, due apparently to affection of the nervous apparatus of the heart, may be observed. The most characteristic is a remarkably slow rate (50 or less). In other cases the heart becomes irregular or intermittent, and there may be attacks of palpitation, which cause the patient much alarm and distress. In cases presenting either form of disturbance of cardiac rhythm syncope may occur, and may be fatal. Attacks resembling angina pectoris have also been observed, and sudden death may be brought about by myocardial degeneration. The duration of the febrile period varies from one to nine or ten days, but is usually three, four, or five days. The maximum is, as a rule, only maintained for a few hours. The fall is sometimes rapid: a distinct crisis, accompanied by profuse sweating, occurs, and the temperature declines to the normal, or even lower, in twelve hours. In other cases the fever has a remittent character, with regular daily fluctuations by which the temperature returns to the normal in two or three days.

Though it is usual to observe a well-marked rise

of temperature, it is important to recognise that no increase in the temperature may ever be detected, although the other symptoms of the attack may be fairly well marked and the sequelæ serious. During the acute stage the patient experiences great depression and lassitude—symptoms which persist after the pain and pyrexia have disappeared, and are often aggravated by insomnia; in some cases convalescence is prolonged for weeks, or even months, and occasionally well-defined melancholia develops. The prostration is accompanied by anæmia.

Among the more severe cases of this type two clinical forms may be distinguished, the comatose and the delirious (Judson Bury). In the former the patient, with or without recognised symptoms characteristic of the onset of influenza, gradually becomes drowsy and apathetic; he answers questions with difficulty, and in a few days becomes comatose. Recovery may occur, but a fatal termination is, according to Bury, more common. Examination of the brain, *post mortem*, may reveal nothing abnormal, or there may be congestion of its surface, or a purulent meningitis, with or without encephalitis, which is usually hæmorrhagic. In cases that recover, and in those in which no morbid changes are found *post mortem*, it must be assumed that the symptoms were produced by cerebral toxæmia, or that any definite lesions which existed were slight or temporary. The meningitis may be secondary to suppuration in the middle ear, or nasal cavities, but may occur independently. Cerebral abscess, when it occurs as a complication of influenza, would appear to be almost invariably secondary to otitis. In the other severe form, the delirious restlessness, irritability, delirium, and even mania are the essential features, or delirium may alternate with a melancholic condition. Spinal meningitis may accompany the cerebral meningitis, but has been known to occur alone also.

Of the nervous disorders which may occur after an attack of influenza, but are perhaps particularly prone to ensue on the nervous type, it can only be said that they include inflammation, degeneration, or functional derangement of every part of the nervous system. Thus in relation with the brain we may have cerebral hæmorrhage, embolism, and thrombosis of arteries, veins or sinuses, meningitis, or encephalitis, dementia, mania, melancholia, hysteria, epilepsy, catalepsy, and neurasthenia. In relation to the spinal cord we may find myelitis or degeneration of any of its various tracts, and disseminated hæmorrhagic myelitis has also been recorded. Finally, to quote Bury again, 'we may have neuralgia or neuritis in the territory of nearly every cerebral or spinal nerve as well as the different forms of multiple neuritis.' Peripheral neuritis may come on days, or even weeks, after the acute symptoms of the febrile stage have ceased. There is pain in the affected limbs, with weakness of certain muscles, dyæsthesia, with reflexes at first increased but afterwards diminished, though never, it is said, abolished. All four limbs may be involved, or two on the same side, or one only. The muscles most often affected are, in the upper limb the scapulo-humeral, in the lower the anterior muscles of the leg and the flexors of the knee. In severe cases the muscles waste rapidly, and may present the reaction of degeneration. In other cases symptoms of disorder of the bulbar nuclei or of their nerves occur with or without derangement

of spinal nerves. The symptoms resemble those due to diphtheria, but are much less regular in their distribution. Paralysis of any of the external ocular muscles may occur either alone or in various combinations. Paralysis of accommodation or transitory dilatation of one pupil may be observed either as an isolated phenomenon or as a part of a more wide-spread affection. Affections of the optic nerve are rare; the most frequent is retro-bulbar neuritis, but papillitis and neuro-retinitis have been observed. Pharyngeal and laryngeal palsies have also occurred, but are uncommon. Loss of the sense of smell and impairment of taste are not uncommon sequelæ, and may persist for long periods. The prognosis in post-influenzal neuritis is good on the whole, even in cases in which the paralytic symptoms are extensive, and the atrophy well-marked; but recovery may be very tedious.

Febrile Type.—A febrile type may conveniently be recognised to contain those cases in which the patient suffers from a febrile paroxysm or from remittent or continued fever with the usual concomitant symptoms, but without catarrh or localised nervous symptoms. In one form of this type, which is perhaps more common in children than in adults, the patient complains of malaise, and the temperature is found to be 101° or 102° ; the thermometer rises rapidly to 103° , 104° , or even 105° , and the patient suffers from headache and is drowsy. In severe cases the drowsiness may deepen to stupor. As a rule the temperature falls as rapidly as it rose, and the whole attack may be over in twenty-four hours, leaving perhaps some depression for a few days. In other cases the temperature, without attaining so high a point, remains for many days or some weeks either of the continuous or remittent type. Cases of the former kind may simulate enteric fever, and it is important to remember that influenza may be immediately succeeded, without defervescence, by enteric fever, the disturbance produced by the former having so diminished the resisting power that the infective agent of the latter, previously present in the body or in the environment, is enabled to develop.

COMPLICATIONS AND SEQUELÆ.—Many of the systemic disorders already described might be regarded as complications of the primary fever, but bacteriological evidence appears to confirm the view, founded on clinical observation, that they are more justly considered to be symptoms of the disease and produced directly by the specific virus. At the same time it must be recognised that an attack of influenza may have a most injurious effect upon chronic maladies, so that pulmonary tuberculosis, for instance, which had become quiescent, may again become active, or that the way may be opened to secondary infections producing for instance otitis, suppurative rhinitis or pharyngitis, or greatly aggravating a tendency to chronic bronchitis. The list might be indefinitely extended. Attention will only be directed to a few of the more serious and frequent complications and sequelæ to which reference has not already been made.

Insanity is said to be a frequent sequela of influenza. See INSANITY IN SPECIAL DISEASES.

Albuminuria is observed in a considerable number of cases. It may come on during the acute attack, and endure for several weeks or months. There may be merely a trace of albumen at an early stage, with a microscopical amount of blood, and hyaline casts containing a few blood-cells or granules,

or small granular casts, in the centrifuge-deposit. In other cases acute degeneration of the kidney, acute nephritis with in some instances involvement of the glomeruli, or acute hæmorrhagic nephritis occurs. Chronic diffuse nephritis is occasionally a sequel of influenza, and cases of so-called functional albuminuria are aggravated.

Arthritic pains are common during the acute attack, and may be accompanied by tenderness and swellings. These affections are commonly spoken of as rheumatic, but it may be doubted whether they have any relation to rheumatism, though pericarditis and endocarditis have been noted as occasional complications of influenza. Phlebitis, especially of the smaller veins of the foot and leg, is not rare as a sequel of influenza, and occurs perhaps especially in persons of a gouty diathesis.

The *cutaneous* lesions which have been attributed to influenza are numerous. Reference has already been made to the erythematous rash sometimes observed at the onset; occasionally a fine papular rash has been seen at the same period. Herpetic eruptions affecting the lips or other regions occur with considerable frequency. Purpura has also been observed. The erythematous and papular rashes are usually succeeded by fine desquamation, but occasionally a remarkable desquamation in large sheets has been observed.

Stomatitis may complicate the respiratory or gastro-intestinal form and cause a great deal of distress. It is usually of the so-called follicular variety, the primary lesion being quickly followed by ulceration which may extend until large areas are continuously involved.

RELAPSES AND REPEATED ATTACKS.—It has been estimated that a relapse occurs in 10 per cent. of all cases; it is at least very common. After four to six days of freedom from fever the temperature again rises and all the symptoms recur. As many as three such relapses have occurred. Second attacks are very common, and it is certain that the immunity produced by an attack lasts only a short time. It has sometimes been observed that a person who has suffered from one type of this disease during one epidemic suffers from another during the next, even though the prevalent form may be of a different type; but no rule can be stated.

DIAGNOSIS.—Except during the prevalence of a well-marked epidemic the diagnosis of influenza may be exceedingly difficult, and must usually be reached by a process of exclusion. A slight attack, particularly if of the respiratory type, may pass almost unobserved, the symptoms being attributed to 'a common cold,' but its true nature may be made apparent by the mental and nervous depression which succeeds.

In the early stage of an attack of the catarrhal type, the coryza, headache, and fever may, especially if there be discrete erythema of the face and chest, lead to a suspicion of measles; in other cases where pharyngitis is a prominent symptom and erythema is extensive, the case may for a short time present a considerable resemblance to scarlet fever, but in either a few hours' observation will usually make clear the diagnosis from measles or scarlet fever. Occasionally pharyngitis due to influenza is attended by false membrane on the tonsils. This is usually limited to the mouths of the follicles, at least at first, and is then semitransparent and easily detached. Bacteriological examination showing the absence of the Klebs-Löffler

bacillus will confirm the diagnosis. The resemblance which cases of the gastro-intestinal type may present to enteric fever has already been noted. The absence of characteristic stools, of the enteric exanthem, and later on of Widal's reaction, will usually allow a diagnosis to be made.

PROGNOSIS.—The prognosis in childhood and maturity of cases uncomplicated by pneumonia is always good. In aged persons, in those prematurely old, especially if the subjects of emphysema and chronic bronchitis or alcoholism, the prognosis is more serious, as in them complications, in the one instance great aggravation of the bronchitis, in the other cardiac failure, are apt to develop. In any case the prognosis must depend to a very great extent upon the early enforcement of suitable treatment.

TREATMENT.—The most important point in the treatment of influenza is to induce the patient to recognise that the affection may easily become serious, and to persuade him to remain in bed during the acute stage; to this some would add two days in bed after the temperature has become normal, and the precaution is a wise one, at least in persons who are past middle life or prone to bronchitis. It is often difficult to induce a vigorous adult to give up work early enough, as at the onset there is commonly a good deal of excitement and restlessness. The advice should, however, be strongly enforced, for a patient who fights against the disease in its early stage is more likely to suffer from severe pulmonary complications, while a too early return to work after the subsidence of acute symptoms or neglect of precautions against cold and over-exertion during convalescence may lead to relapse or to various pulmonary or nervous sequelæ.

The best routine remedy for the relief of the muscular and joint-pains and backache, with which the disease so commonly commences, is probably sodium salicylate, though phenazone or phenacetin is useful, and perhaps preferable when headache is severe. If there is nausea the drug selected should be given in an effervescent mixture. Quinine may also be prescribed with advantage in this stage, as well as later on in cases in which the temperature becomes or continues elevated or of intermittent type. In attacks of moderate severity the pains in the back and limbs diminish, or disappear after the patient has grown warm in bed, and reaction may be encouraged by hot drinks. When restlessness or insomnia persists after relief of pain, bromides may be prescribed, and in weakly individuals ammonium bromide should be selected. In such persons and in children depressing remedies should be avoided. A great number of other drugs have been highly praised from time to time, among which sodium benzoate and carbonate, cinnamon, carbolic acid, and phenocoll hydrochlorate may be mentioned, but none appear to have come into general use.

It is inadvisable to give a purgative in all cases at the commencement of treatment, though there need be no hesitation in doing so if there be constipation. Calomel followed by a saline draught, and in weakly persons and young children castor oil, are the best drugs to use for this purpose. Where the symptoms point to an attack of the gastro-intestinal form it is wiser as a rule to eschew purgatives and to prescribe a simple enema or at most a moderate dose of castor oil. The diarrhoea characteristic of this form is often very difficult to treat, and for some

weeks any solid food taken into the stomach is followed by painful intestinal peristalsis and an evacuation, even though the appetite may have been in great measure regained. The administration of digestive ferments, of acids and alkalis, of bismuth, or of sedatives commonly has little effect, and the only effective treatment is to direct the abdomen and thighs to be warmly covered and to reduce the diet to broths, soups, and milk thickened with corn-flour or fine oatmeal and spiced. As soon as these can be taken without subsequent discomfort, additions may carefully be made to the diet, the patient's sensations being the best guide.

When convalescence is established tonics should be given, of which the best is strychnine, and when depression is marked the amount prescribed should be increased until a full dose is taken. The diet should be simple and nutritious, and when the weather and social conditions are favourable change of air should be recommended, but not otherwise, as rest, quiet, warmth, and ease are among the chief necessities.

It is not proposed to discuss here the treatment of the pulmonary and nervous affections accompanying or following influenza, as this may be best considered in the articles on BRONCHITIS; LUNGS, INFLAMMATION OF; NEURITIS, &c.

The *prophylaxis* of influenza when the disease has become thoroughly established in a community is difficult. If the first case in a household can, in the earliest stage, be isolated by being confined to a room with a nurse in attendance, the dissemination of the infection to other members of the household will probably be prevented; and if this system could be applied generally throughout a community much might be done to prevent the development of an epidemic. But in practice the earliest cases are rarely isolated, either because the patients consider that they are suffering from 'a common cold' or because they refuse to remain in bed, or even to refrain from going about their ordinary business. Much may however be done to protect old and delicate persons from risk of exposure to infection.

DAWSON WILLIAMS.

INFUSION.—See SALINE SOLUTION, Infusion of.

INHALATIONS, Therapeutic Uses of (*inhalo*, I breathe in).—Inhalation is a method of applying remedial agents to the respiratory tract, whereby these substances in a gaseous or atomised form are brought into contact with the mucous membrane of the nose, mouth, pharynx, larynx, and bronchi, and may even penetrate to the epithelium of the air-cells. The examination of the lungs of colliers, grinders, and others engaged in dusty occupations has shown that the inhaled dust can be detected in the lung-tissue, where it induces chronic pneumonia. The experiments at the Académie de Médecine proved that medical sprays are equally penetrating.

METHODS.—The modes of inhalation vary with the drug used, depending mainly on the temperature at which it volatilises, and also on the medicinal effects aimed at.

Chloroform, ether, bichloride of methylene, and nitrite of amyl evaporate at ordinary temperatures, and only need to be diluted with air to be safely inhaled. Calomel and sulphur are sublimed at high temperatures in special apparatus; but the majority of drugs are best vaporised through the medium of

hot water or steam, or reduced to fine spray by passing compressed air through their solutions.

Many forms of inhaler are in use, but in selecting one for warm inhalations the requisites are—(1) that it can be used without difficulty by the patient; (2) that a temperature of 130° to 150° F. can be steadily maintained; (3) that the steam be thoroughly impregnated with the medicament; and (4) that the inhaling-tube be fitted to the nostrils as well as to the mouth, so as to ensure a sufficient supply of the inhaled vapour. Lee's steam-draught inhaler is especially useful for projecting a full current of steam into the throat and air-passages. The force and temperature are alike controlled by the sliding valve on the inhaling-pipe. When no inhaler is at hand, a jug with a wide mouth, and half filled with hot water, may be used, a towel being placed round between the mouth and nose of the patient and the opening of the jug, to prevent the escape of the vapour into the air.

VARIETIES AND USES.—Inhalations are employed chiefly in diseases of the pharynx, larynx, and air-passages, and may be classed as *sedative*, *stimulant*, and *antiseptic*.

Sedative.—Steam is soothing to the throat, when this part is dry, inflamed, or irritable. In incipient laryngitis and croup, as well as in irritable bronchitis, the inspiration of steam from specially arranged kettles is very grateful, the moist vapour promoting secretion and expectoration.

Jets of steam are used in hospitals and bathing establishments as vehicles for the inhaled drugs, and are directed into the patient's mouth.

A sedative inhalation made of one part of chloroform and two or three of rectified spirit—of which one teaspoonful may be added to a pint of water, at 60° to 100° F.—is much commended in hay-fever and laryngeal spasm. It must be remembered that chloroform is very powerful when given with steam as an inhalation. One drop of chloroform in a pint of water at 150° may produce giddiness.

Stimulant.—Stimulating moist inhalations can be prepared with various volatile oils. Oils of pine and of cubebs are useful stimulants in cases where there is much secretion from the throat and air-tubes. Thus 2 drachms of oil of pine or oil of cubebs may be mixed with 60 grains of light carbonate of magnesium in 3 ounces of water; and of this mixture 1 drachm may be used in a pint of water at each inhalation. One drachm of the compound tincture of benzoin, in half a pint of hot water, is often useful in chronic bronchitis and laryngitis. Oil of turpentine or the Vapor Olei Pini Sylvestris of the Pharmacopœia makes an excellent stimulant inhalation in cases of dilated bronchi.

Antiseptic.—Antiseptic inhalations are used where the object is to correct a fetid secretion, as well as to stimulate the secreting membrane to fresh action. In fetid bronchorrhœa, in gangrene of the lung, in fetid abscess, and in pyo-pneumothorax, benefit is derived from a vapour of creosote or of iodine, or from glycerine of carbolic acid (2 to 3 drachms to a pint of boiling water), or again from oil of thymol, prepared like the other essential-oil vapours, with light magnesia (60 grains to 3 ounces of hot water). Carbolic-acid vapour can be well diffused in a room by mixing the acid with water in Lee's steam-draught inhaler, or by dropping the acid on a hot metallic plate. Creosote or eucalyptus oil, mixed with an equal quantity of ethylic alcohol, is often employed in the form of drops (10 to 20 drops

at a time) on a small sponge placed in a perforated zinc respirator. The respirator thus charged is worn by the patient for one hour morning and evening, with a view to improving the state of the lungs. After a free morning expectoration the respirator-inhaler should be used, and instruction given to inspire deeply by the mouth and expire through the nostrils with the mouth closed.

Antispasmodic.—The fumes of burning nitre-paper are employed as inhalations in cases of pure spasmodic asthma uncomplicated with bronchitis. The paper—prepared by soaking white blotting-paper in solution of nitrate of potassium (30 to 40 grains in an ounce of water)—is sometimes washed over with tincture of benzoin, and this, in certain cases, may be an improvement; but in ordinary forms of asthma the nitre-paper, burnt till the patient is enveloped in smoke, will usually relieve the asthmatic paroxysm. The fume of a grain of powdered opium volatilised on hot metal has been praised as a remedy to cut short nasal catarrh; as well as smoking solid opium in the Chinese fashion through a pipe, in spasmodic asthma. Cigarettes, pastilles, and powders containing stramonium, belladonna, and other antispasmodics, are well known as remedies in spasmodic asthma.

Inhalations of atomised spray have of late years come into deserved repute as valuable aids to the treatment of chronic diseases of the throat and lungs. The principle of the hand-ball and steam-spray atomisers is that, if two capillary tubes are placed at a certain angle to each other, one dipping into a fluid, while through the other a stream of air is driven by heat or compression, a vacuum is formed in the first, causing the liquid to pass out in the form of fine spray. In using these instruments, the operator should seek to blow the spray into the patient's throat at the time when an inspiration is being taken, as thus the spray will obtain a free entrance through the larynx into the trachea. It is doubtful if much spray enters the air-tubes; some certainly does, as has been stated above, but the cold sprays do not appear to afford so much relief to affections of the lungs as the warm inhalations. In cases of tumidity of the larynx, a spray containing 10 grains of alum to 1 ounce of distilled water may be used. In place of alum, 2 grains of sulphate of iron, 5 grains of sulphate of zinc, or 5 grains of dry perchloride of iron, in 1 ounce of water, may be employed. For antiseptic purposes, 5 minims of sulphurous acid, or 1 minim of carbolic acid, to 1 ounce of water, or a like quantity of solution of iodine, may be used. In putrid sore-throat and diphtheria the writer has seen excellent results from iodine, either inhaled in vapour or applied in solution. As a styptic and hæmostatic spray 50 to 200 grains of tannic acid are employed, dissolved in 10 ounces of water, but for relaxed throat a weaker solution is useful. For sedative purposes a solution of bromide of ammonium, or one containing half a grain of acetate of morphine to 1 ounce of water, may be employed. Diluted ipecacuanha-wine spray is said to be very efficacious in relieving the dyspnoea of chronic bronchitis and emphysema. This spray in a few instances may induce vomiting, but this accident may be obviated by diluting the wine with a considerable proportion of water. All these spray-solutions should be filtered through paper, otherwise they may contain small particles which clog the aperture of the atomiser. At the Continental spas it is usual to

medicate large chambers by means of sprays and vapours, in which patients can sit for hours breathing the artificial atmospheres; and in this way various mineral waters, such as those of La Bourboule, Aix-le-Bains, and Cauterets, are locally applied.

An inhaler should give a cloud of fine spray. This can be ensured by driving the spray against the sides of a strong glass globe with such violence that it is broken into very fine particles, and these can be deeply inhaled through the mouthpiece without causing irritation, and often with very great comfort to the patient.

Insufflation is a method of applying powders to the larynx. A vulcanite tube curved at a suitable angle is carried over the tongue to the laryngeal aperture, and then the powder which has been introduced through a small opening covered by a slide in the tube, is blown into the larynx and trachea. The blowing is effected sometimes by an elastic ball at the end of the tube, at other times by the mouth of the operator. In laryngeal phthisis $\frac{1}{20}$ to $\frac{1}{4}$ of a grain of hydrochlorate of morphine, mixed with sugar of milk, may thus be blown into the larynx, and often with great comfort to the patient. A grain of iodoform and a grain of boric acid are often added to the morphine powder.

JOHN C. THOROWGOOD.

INOCULATION (*in*, into; and *oculus*, a bud, a graft).—As a medical term, inoculation is either an operative procedure or an accidental occurrence, by means of which infective materials are brought into direct contact with the minute vessels of the skin or of a mucous membrane, or with those of the subcutaneous or submucous tissue, so that they are readily and speedily absorbed. See INFECTION; IMMUNITY; VACCINATION; HYDROPHOBIA; PLAGUE; and TYPHOID FEVER.

INSANITY.—SYNON.: Fr. *Folie*; Ger. *Geisteskrankheit*; *Geistesstörung*.

The articles arranged under this heading comprise the following:

I. General Considerations regarding ætiology, symptoms, diagnosis, prognosis, and treatment, p. 747.

II. Pathology and Morbid Anatomy of Insanity, p. 751.

III. Developmental Insanity, p. 757.

IV. Insanity of Pregnancy, the Puerperal Period, and Lactation, p. 758.

V. Senile Insanity, p. 761.

VI. Delusional Insanity, including Paranoia and Monomania, p. 763.

VII. Imperative Ideas, p. 765.

VIII. Impulsive Insanity, p. 765.

IX. Mental Stupor and Catatonia, p. 766.

X. Moral Insanity, p. 767.

XI. Insanity in Special Diseases, that is, Insanity occurring in the course of ordinary Medical Diseases, p. 768.

The following is a list of articles relating to this subject arranged under their respective headings in other parts of the Dictionary: ALCOHOLISM; CATAPLESY; CHILDREN, TRAINING OF; CIVIL INCAPACITY; CLIMACTERIC INSANITY; CONSCIOUSNESS, Disorders of; CRETINISM; CRIME, IRRESPONSIBILITY FOR; DEMENTIA; DIPSOMANIA; EPILEPTIC INSANITY; FEIGNED DISEASES; FOLIE CIRCULAIRE; FOLIE À DEUX; FORCIBLE

FEEDING; GENERAL PARALYSIS OF THE INSANE; HYSTERICAL INSANITY; IDIOCY; LUCID INTERVALS; LUNACY, LAW OF; MANIA; MELANCHOLIA.

I. General Considerations.—For the healthy function of the brain it is necessary that all the component portions shall be in a sound condition working harmoniously as a perfect whole. The grey and the white matter, the blood-vessels, lymphatics, and neuroglia all play important parts, and must be free from defect. They must not be stunted or arrested in development, the blood must be of healthy quality, not too much or too little, not contaminated by alcohol or other poisons. The brain-cells must not be overworked or damaged by blows, heat, or organic lesions. For the *sana mens* there must be the *sanum cerebrum*.

ETIOLOGY.—**I. Predisposing causes.**—**Heredity.**—The one great predisposing cause of insanity is an inherited tendency to neurotic disorder. Though all writers recognise this tendency, they vary much with regard to the importance to be attached to it and in the statistics they give, one observer attributing ten per cent. of cases to this cause, another no less than ninety. The discrepancy arises from the fact that some take into account insanity only and not other neurotic disease such as epilepsy or dipsomania: one man reckons only those whose insanity is inherited in the direct line from father or mother, while another looks not only to the direct line, but also to the collateral branches. The difficulties of the investigation are enormous when we go back even to three generations. The history of two grandfathers and two grandmothers is hard to ascertain with anything like exactness, but to go further back and examine the records of four great-grandfathers and four great-grandmothers is well-nigh hopeless. No accurate information can be got by questioning, for such questions are evaded, or a direct negative is given, whatever be the facts. Only from our own observation can we form conclusions, and this is limited to a few generations. In families where insanity is known to exist, many of the members are sane and remain sane all their lives. We require to know why some escape and others break down, not only in insanity but in epilepsy, hysteria, hypochondria, neuralgia, dipsomania, or other neurosis. The tendency is not eliminated by those who themselves escape insanity, for by reason of *atavism* or *latency* it may reappear in the children of parents who have shown no symptoms. This has a grave bearing on the marriage of cousins or other persons in whose family insanity has developed. It is essential that all the predisposed should marry healthy partners whose family history is good, and who themselves are free from neurotic disorder or threatenings thereof.

In many persons the inherited predisposition or tendency is manifested not by insanity but by eccentricity of various kinds, so that they differ from ordinary members of society and are badly adjusted to their environment, not so completely out of harmony as to require restraint, but always on the verge of becoming so. They may go through life in this condition or break down, eccentricity merging into insanity. They form the large class of borderland cases, and are often extremely difficult to deal with. Many drink, and their mental state is ascribed to drink; but frequently the drinking-habit is an inherited neurosis. They all display

the predominance of the egoistic or subject-consciousness which is such a marked feature both in the insane and those in the borderland. Some evince an intense selfishness shown in penurious habits, a desire to amass wealth for which they stint themselves and families. If anything goes wrong with their affairs and they experience a loss however trifling, they deplore their misfortunes, say they are ruined, and become melancholic. Others live in a state of constant suspicion, suspect everything and every one, their medical man, their clergyman, or lawyer. They think their tradesmen are trying to cheat them, and will listen to all the gossip of servants or the like. A third group make life miserable by intense jealousy; even the young will display this egoism, and are jealous of any one who comes between them and their friends. In married life incredible jealousy is found in those who pass as sane. Men and women make their lives intolerable without the faintest ground. Other people live in a state of perpetual fear and apprehension, take a gloomy view of everything, and continually think that something amiss is going to happen. Others are hypochondriacs, spending their lives in the vain search for remedies for imaginary ailments, neglecting their business, family, and friends.

Some of these eccentrics drift into insanity, but many persons develop symptoms of the disorder without any previous peculiarity or warning. The time of life is held to be accountable for it in certain cases, and there has been described an insanity of *puberty* and *adolescence* which above all is due to hereditary taint (see INSANITY, DEVELOPMENTAL). The period between 20 and 30 is far more productive of insanity than that preceding, but between 30 and 40 the liability is greatest, for this is the time of the highest development and specialisation of the brain-centres, a time when an inherited weakness may assert itself, and when also an *acquired* insanity may arise from overstrain, alcohol, or syphilis, which at an earlier age do not play so important a part. Yet the insanity of this period has received no name. As age advances the insane cases are less frequent, but the *climacteric* is a time of danger (see CLIMACTERIC INSANITY). Old age has also much to do with the causation of insanity, but if we eliminate the cases of mere mental decay and degeneration, we shall find that heredity is often the chief cause, and in many has produced previous attacks (see INSANITY, SENILE). Heredity is a very important factor in the production of insanity during pregnancy, the puerperal period, and lactation. See INSANITY OF PREGNANCY, the PUERPERAL PERIOD, and LACTATION.

Sex.—That females preponderate in our asylums is certainly owing to the lesser mortality, for they are much less liable to fatal brain-disease. Probably the difference in the number of the two sexes who become insane is not very material, but statistics help us little, as only those of new cases can determine the question.

Age.—The time of life at which most insanity occurs is that of maternity, between thirty and forty years of age; it then decreases with each decennial period. The time of the highest development of the brain-centres is that in which they are most prone to disorder, the time when an inherited weakness is most likely to manifest itself, and when the last and least organised structures are most liable to disturbance and loss of equilibrium.

II. Exciting Causes.—These have been divided into *physical* and *moral*, and by *moral* is meant *mental*. The *physical* are, in the opinion of many, toxins either derived from without or generated within the body. Such toxins as those of rheumatism or gout are easily recognisable, and the relationship between them and insanity is unquestionable. Disease of the kidneys is known to be connected with brain-disorder and causes uræmic convulsions and uræmic coma; diabetes may end in coma, and disturbance of the liver may permit toxins from the intestinal canal to reach and affect the brain. So also the toxins of fevers, of typhoid fever or scarlatina, of influenza or pneumonia may light up insanity in some, and ordinary delirium in others. What the connection may be between the uterus and the brain is a disputed point, and it may be doubted whether puerperal insanity is always due to sepsis as some hold, while other toxins depending on disease or disorder of bodily organs have yet to be defined. Besides these autotoxins from within there is a large mass of insanity caused by poisons from without which is due to the vices of civilisation and is preventable.

Alcohol.—Alcoholism probably plays a larger part in the causation of insanity and an insane inheritance than any other factor, and this is the reason why cerebral disorders increase among the lower rather than the upper classes. See ALCOHOLISM.

Syphilis.—Among the preventable causes of insanity syphilis holds a prominent place, and its importance is emphasised daily by the researches of pathologists. General paralysis of the insane is mainly due to syphilis, acquired or inherited. Many other brain-disorders and lesions of the cerebral vessels have their origin in syphilitic disease.

Lead, bang, opium, cocaine, &c.—Among the preventable causes of insanity must be ranked lead-poisoning, such cases occurring principally in manufacturing districts (see LEAD-POISONING). Many recover, but some drift into dementia, having gone through various stages of mania or melancholia. In the East or wherever Orientals are gathered together bang, hashish, or Indian hemp is a fertile source of insanity. The Superintendent of the asylum at Cairo reports that in 41 per cent. of his male patients bang alone or combined with alcohol caused the disease. Drugs like opium, morphine, cocaine, chloral hydrate, and other hypnotics may bring about a habit which amounts to a disease, but if the poison is removed actual insanity is rarely found.

In the search after toxins we must not forget that there are other and equally potent causes. These have been called *moral*, but a better name for them is *mental causes*. They bring about insanity, not by toxins but by disturbance of the brain-circulation and vessels, by alteration of the blood-supply, not in the quality but in the quantity. We know that mental excitement, even when pleasurable, prevents sleep by producing hyperæmia. In health this quickly subsides, but if long-continued worry and overstrain render this sleeplessness constant, chemical changes are set up and the brain-cells are damaged by fatigue as those of the spinal cord are by overwork and strain. We cannot disregard the importance of such hyperæmia leading to congestion and the accumulation of the products of waste.

Sudden fright or shock may bring about rapidly the changes which are slowly caused by long-con-

tinued strain. How the circulation is affected by such events is shown by the fact that occasionally sudden shock will produce cerebral hæmorrhage.

Stroke and traumatism.—Many break down in India and are said to have had sunstroke. A better name is heatstroke, for the cause of the insanity is exposure to the heat of the hot season, night and day, and consequent pneumonia. *Traumatic* insanity may be due to a blow causing organic change, or to shock. In the latter case hereditary predisposition is almost certain to be found.

Epilepsy.—A considerable amount of insanity is due to epilepsy. See EPILEPTIC INSANITY.

SYMPTOMS.—The first symptom of insanity is an *alteration* in the feelings or conduct of the individual. He feels that something is amiss, as in truth there is. There is a defective condition of his nerve-force and a reduction of the highest mental centres, but this he does not realise, and proceeds to account for his feelings by external causes. He imagines that something has been put in his food, or, feeling himself to be changed, thinks that every one is looking at him or conspiring against him. The stage of *alteration* may be long or short, and during it his conduct and feeling may be changed, but in the great majority of cases it does not last long without *delusions* which arise out of, and represent, the feeling experienced. Delusions are not the first symptom of insanity; they are preceded by the altered feelings, so that when we find delusions it is probable that the disorder has lasted for some time, and on inquiry we hear that he has complained of his head, that his nights have been sleepless, his appetite impaired, and his digestive apparatus disordered. The first stage of insanity in most patients is one of depression. This at first may be slight, and may pass off with rest and treatment, or it may increase till it becomes a grave melancholia with suicidal tendency requiring active measures. In a certain number the depression is succeeded by exaltation and excitement. This may point to serious cerebral mischief and commencing general paralysis. The reduction here is to a greater depth than in the melancholic, and the prognosis is less favourable, even if there be no symptoms of general paralysis.

Generally speaking, then, we find delusions present in insane persons; and it is to be remembered that delusions always concern the patient personally. Mistaken beliefs, beliefs in mesmerism, spiritualism, or ghosts, mistaken beliefs or popular fallacies about health, these are not insane delusions unless the person who holds them believes that they concern him, and make him act in some insane way. Those most commonly found are delusions that there is something amiss with the patient. Either he has some loathsome disease, as leprosy or syphilis, or he is poisoned by something put in his food or drink, or he is very wicked and going to be tried and punished or tormented or burnt. Many, especially women, are troubled by fears that they have been so wicked as to destroy their hope of salvation in the life to come, and many think not that they are wicked but that others are plotting and conspiring to ruin them, to rob them of money and character, and to accuse them of every kind of possible crime. This is the well-known *monomania of persecution*. On the other hand where there is exaltation of ideas and excitement and hyperæmia of brain, the patient will think himself immensely rich, strong, and of high rank. He will invent machines or paint pictures to bring him unbounded wealth. He will be

restless, incessantly moving about to carry out his projects, and requiring legal restraint to keep him quiet. These exalted ideas are common in general paralysis, but they are also found in ordinary mania.

Hallucinations of the senses are also frequently found in the insane, especially those of *sight* and *hearing*. The former occur in the acute rather than in the chronic stages of insanity, and pass away with the acute period, as in delirium tremens. But hallucinations of hearing 'voices' are met with in both the acute and chronic insane, and may remain when all other symptoms have subsided, or if they vanish they are apt to reappear at any time. Such patients are a dangerous class, often incurable, and under the influence or command of the voices may commit crimes or suicide.

Insane acts.—Although in the great majority of insane patients delusions are found, yet the insanity of some is shown by insane conduct without apparent delusion. This class often presents great difficulties when restraint is needed, for it may be alleged that the act proceeds not from insanity but from vice. There may be such acts as indecent exposure, fantastic dress, solitary living or peculiar habits, dipsomania, homicide or suicide, self-mutilation, wasting or squandering of property or stealing. This will be discussed under MORAL INSANITY and IMPULSIVE INSANITY. The patients who commit insane acts do them chiefly under the influence of delusions, or they may not have arrived at the stage of delusion. Stealing, for example, is common at a very early period in general paralysis. Others may have lost their delusions but not wholly recovered, while patients may show the first signs of dementia, senile or epileptic, by foolish and insane conduct.

DIAGNOSIS.—A great number of patients who come before the physician for treatment present no difficulties of diagnosis. A man in acute mania or acute melancholia may be difficult to treat, but diagnosis is easy; and in cases of suspected general paralysis there may be no doubt about the insanity, although there may be as to the precise nature of the disease. Diagnosis is difficult in cases of so-called *partial insanity* where a patient with perhaps fixed delusions is able to conceal or deny them, and to talk rationally on ordinary topics. Information has to be gained from friends, and according to their views and inclination they will magnify or minimise the symptoms they have to describe, and frequently obstruct rather than aid the inquiry. The patient is said to have delusions; it is important to ascertain accurately whether that which is alleged is a delusion or a fact. If it is a delusion, is it an insane delusion and one which justifies the signing of a certificate? Also, does the patient hold the delusion at the time of the examination? Frequently we hear of a delusion held perhaps a month previously which has afterwards passed away. Where delusions concerning conspiracy or poison prevail, inquiry concerning the patient's health will often elicit them, and questions about the family or friends may bring to light delusions of conspiracy and persecution. Where there is exaltation and reckless expenditure it is often difficult to come to a decision. The alleged lunatic may spend more than he ought, yet not so much as to make it an undoubtedly insane act, and we may not be able to get at any delusion. Here a decided change may be noticed, a change in habits and feelings, which very often is the surest mark of insanity. The difficulties of dia-

gnosis arise chiefly in cases where the unsoundness of mind is of a negative rather than a positive character, an insufficiency of mental power rather than an aberration. Medical men are frequently called upon to say whether a person of weak mind, who is not a lunatic in the ordinary sense of the word, is or is not capable of taking care of himself and his affairs. Such questions often arise in forensic contests, and counsel argue that because there are no delusions nor the symptoms of ordinary insanity, therefore the alleged lunatic cannot be held to be of unsound mind. One class of these persons is that of the weak-minded or imbecile who have been deficient from birth or childhood. Here the difficulty is to determine the degree of the defect. They are not idiots, but something perhaps not far removed. They are often wicked and vicious, and it may be necessary to protect their persons as well as their property. They constitute a portion of the *morally insane*, may have a certain amount of education, an excellent memory, and are sharp and cunning in many ways. But they, notwithstanding, may have no idea of the value of money beyond that of half a crown, and know nothing of capital, interest, or income, being obviously at the mercy of any designing man or woman. There are others whose imbecility does not date from childhood, but has been caused by attacks of insanity, apoplexy, epilepsy, or drink. Here the difficulty is lessened, inasmuch as we have a standard of comparison in the patient's former condition which we have not in the congenital imbecile. A marked symptom is loss of memory, a common result of epilepsy and drink. But this also is a question of degree; and many can tell us all about their childhood and school-days who know nothing of what happened yesterday, and if they have made a will are not certain of it, and can tell us nothing of its purport. There is also the dementia of old age, often very painful to deal with if it takes the form of vicious or extravagant habits. Here we must compare the former life of the patient with his present, and we shall probably recognise the change which is so often the best proof of insanity. The difficulty in all these classes is greater if we have not known the individual previously. Then our comparison is with a former condition, only known by hearsay, which will be influenced by the friends according to the direction they wish our opinion to take. This unsoundness of mind is observed in persons whose insanity is not marked by delusions but by conduct, and much of it depends on hearsay, for many insane acts, even attempts at suicide and homicide, are not witnessed by the medical attendant but narrated to him. The alleged lunatic must be questioned upon them, and if he justifies them in an insane manner, the diagnosis is easy. If he denies them, further inquiry may be necessary. Perhaps the most difficult of all are cases of dipsomania. There is no law which enables us to subject inebriates to compulsory restraint. They cannot be placed under certificates unless there is evidence of insanity. In delirium tremens there often is such evidence, but it is not wise to send such patients to an asylum, as in a week or less the disorder will come to a favourable or unfavourable conclusion.

PROGNOSIS.—The first question asked by the friends of a patient is, will he get well? If the malady is recent and acute and is not General Paralysis, the answer will be favourable, always

provided that proper treatment be adopted. An asylum may be an obvious necessity, but often this is violently resisted, and it is certain that many curable cases are converted into chronic by improper treatment. If adequate measures are employed, a large proportion of recent cases will recover, even when very acute. No insanity is more acute than the delirious mania of puerperal women, yet the recoveries from this in asylums are 80 per cent. The percentage of recoveries from acute delirious mania in males is not so high, but the majority get well at any rate in the first attack. The prognosis here is whether the patient will live or die. If he lives he will almost certainly recover. The principal points to be observed are the pulse, the tongue, and the temperature. A rapid pulse, a tongue brown or black and dry, and a high temperature are unfavourable. Acute delirious melancholia with obstinate refusal of food is a very formidable disorder, and, as it frequently occurs in patients whose health is already broken, the prognosis is bad. But melancholia of a less acute type is curable beyond any other form of insanity, and this after a long period of depression. Such patients may have the most torturing delusions, the most suicidal tendencies, may continue in this condition for years, and then get quite well. And this is to be borne in mind if legal provisions have to be made. We are constantly asked whether a family history of insanity will prevent a patient's recovery. It certainly does not in the first attack, as is shown by the large percentage of recoveries in puerperal insanity, where hereditary predisposition is generally the cause. The insanity of young persons is mainly due to this, but a large number recover. Such, however, are apt to have subsequent attacks, and many become chronic lunatics later in life. With the exception of the melancholic an unfavourable prognosis must be given in all cases where the duration of the disorder is at all prolonged. All writers are agreed that early recognition and early treatment conduce to recovery. If we are consulted about patients whose insanity has lasted a twelvemonth or longer, the prognosis is bad, especially where the symptoms at first slight have grown by degrees till they have become severe and formidable; those who have hallucinations of hearing of a twelvemonth's duration are unlikely to lose them. Epileptic insanity is unfavourable, because the epilepsy must have been frequent to cause the mental disturbance, and is not likely to cease. Alcoholic insanity may or may not be cured according to its nature and degree. Acute insanity following a bout of drinking may pass off, and as in delirium tremens the patient will recover entirely, but the dementia from long-continued inebriety depending upon changes in the brain-cells and centres is most unfavourable, as are any organic changes produced by syphilis. All recurrence, whether after long or short intervals, is bad. Some patients have alternate days, others alternating attacks of mania and melancholia, with perhaps a short interval of sanity between. Many have recurring attacks of the same kind. The prognosis is unfavourable in all such cases.

TREATMENT.—There are two classes of the insane requiring treatment: those who suffer from acute and curable insanity, and those whose malady is chronic and incurable, who must be kept under more or less restraint for the term of their lives. We are not now concerned with the latter. When

dealing with the former, the first question is, where and by whom is the patient to be treated? It may be laid down as a rule to which there are but few exceptions that an insane person cannot be properly treated at home. If the insanity is not a mere transitory outburst but a prolonged attack with delusions and excitement, maniacal or melancholic, home is the worst place. Removal to fresh surroundings is an imperative necessity, and the sight of near relatives is, generally speaking, as prejudicial as that of the home. Many must be removed to an asylum, some because their means admit of no other course, others because they are too dangerous to be kept in an ordinary house. But there are patients who can be treated successfully out of an institution, and if they are young or are earning their livelihood in a profession or post of responsibility, it is much to their advantage to escape the stigma of a lunatic asylum. Among these are:—

(a) Cases of acute delirious mania, puerperal or other, which often run a short and regular course, and may be treated in a private house if suitable rooms can be provided—cool, airy, and quiet, with windows and fire guarded, under the care of experienced and sufficient attendants. If any relatives are in the house, the patient should see them rarely or not at all.

(b) Melancholic patients whose malady is not acute, who take their food, are clean and orderly, and able to take outdoor exercise, may be treated in private houses other than their own. A friend or relative may be of the party, but strangers are a valuable adjunct. Most melancholics are suicidal, yet adequate vigilance should prevent this. Many are able even to travel, and derive great benefit from constant change of scene.

(c) Young patients suffering from 'acute dementia' or, as it has been called, stupor with dementia (*see DEMENTIA*), need not be sent to an asylum, and may even be treated at home under an experienced and judicious attendant who will carry out the directions of the medical man.

There are some, however, who have a much better chance of recovery in an asylum, and whose malady is likely to become chronic if this treatment is not adopted.

(d) The melancholia of many patients is too acute for residence in a private house. They are on the look-out all day and all night for opportunity of suicide by windows, stairs, or other means; they require forcible feeding, strip off their clothes, and will not lie on a bed. All such demand the appliances and safeguards of an asylum.

(e) There are patients suffering from acute mania, not acute delirium, but conscious mania, who, knowing well what they are about, are noisy and violent, even homicidal, mischievous and quarrelsome, always complaining of the attendants, wilfully wet and dirty. This form of insanity is generally of some duration, the patients require much exercise, but are not fit to walk beyond asylum-grounds, and demand the authority and supervision of an asylum-superintendent, for they cannot be left to attendants only.

(f) Very few general paralytics can be treated out of an asylum. If dementia commences very early and the patients are quiet and tractable, some may be managed in a private house if the friends greatly desire it, but the grandiose exaltation of the majority, the impatience of control and reckless violence, make an asylum necessary. Once

there, they are the happiest members of the community.

(g) There are some whose malady, not being very acute, has been called *partial insanity* or *monomania*. Sometimes it is a form of melancholia marked by suspicion, aversion, delusions of persecution, and general alteration of feeling and conduct. Above all, it is characterised by the most intense egoism. This is the condition of many of the chronic insane, but occasionally the disorder though similar in many respects is recent and curable, and for this an asylum is the most effectual remedy. Because he is not acutely insane or dangerous the friends shrink from such a step, but placed in a family or private house, a patient of this kind becomes the centre and focus of the whole of his surroundings, and his egoistic ideas are fostered accordingly. If he is melancholic, never was man so unhappy, so God-forsaken, so tormented; those about him must assure him fifty times a day that it is not so, and be for ever encouraging his luxury of woe. If he is not melancholic, but the opposite, he never ceases to accuse and revile those about him, and strives to make their lives as uncomfortable as he can. Place one of these in an asylum, where, instead of being the one important unit, he becomes, say, the hundredth part of the whole community, occupying not the entire attention of those who have charge of him, but only a very small part, his self-importance is greatly chilled, especially as his ideas and complaints are totally disregarded by the other ninety-nine inmates. Many thus recover, often without medical treatment of any kind. The asylum carries with it a moral treatment not to be found elsewhere.

With regard to medicinal treatment little need here be said. The medicines appropriate to each form of insanity will be mentioned under the different heads. The chief medicines required are tonics and sedatives, and among the former the most valuable are the preparations of iron, either alone or in combination with arsenic or strychnine. Constipation, which is almost always a trouble in melancholia, must be combated by such drugs as cascara, given at regular intervals, with or without enemata, while massage of the abdomen is often useful. Of sedatives and hypnotics there is a long series. Besides opium and the bromides there are chloral hydrate and chloralamide, sulphonal and trional, hyoscine and hyoscyamine, and paraldehyde, probably the safest of all. Opium is especially beneficial in melancholia, while the bromides are more suited to excited and exalted patients. Chloralamide is preferable to chloral hydrate, trional to sulphonal; hyoscine and hyoscyamine are dangerous medicines, and are rapidly going out of favour. The objection to paraldehyde is its nauseous taste, but it is a safe narcotic with little unpleasant after-result, and may be administered without risk in the majority of cases. The treatment of insanity by the administration of animal extracts, lately so much advocated, has been very carefully carried out at the Royal Asylum, Morningside. Easterbrook has published a detailed account of the patients there treated by various extracts, especially thyroid, and came to the conclusion that these substances produce a general tonic effect upon cell-metabolism. A certain number of patients recovered under large doses of thyroid where previous treatment had been well tried but failed, yet no one recovered from ordinary intractable insanity under small or moderate doses.

In a hundred cases of insanity which were not hopeless there were twelve recoveries.

Good and abundant food is most necessary in the treatment of the insane. A large number, especially the melancholic, refuse food, but must not be allowed to remain long without it. Either by the nose or by the mouth, they must be fed; it is useless to wait in the hope that hunger will induce them to eat, for starvation does not cause hunger in such persons, but on the contrary, adds to their weakness, bodily and mental. When they find out that they will be fed by force, they frequently give in and take their food. G. F. BLANDFORD.

II. Insanity, Pathology of.—During the last six years the pathology of insanity has made very rapid and remarkable advances, which have been coincident with, and in a large measure dependent upon, corresponding advances in our knowledge of the normal structure and physiology of the nervous system. It has also been very greatly assisted in its progress by the precise knowledge that has been gained regarding the behaviour of the nerve-cell under pathological conditions, through the brilliant series of experimental researches carried out by Lugaro, Marinesco, van Gehuchten and others. During this period, moreover, the modern doctrine of the toxic basis of insanity has taken definite shape and steadily grown in importance. The very numerous structural alterations that can be demonstrated by modern methods of investigation in the brains of persons who have died insane are to-day recognised to be, with few exceptions, the result of the action of various toxins, some of which are introduced from without, but most of which are generated within the body itself, either in consequence of perverted functional activity of various organs and tissues, or by micro-organisms.

We shall not here attempt to frame any classification of the pathological varieties of insanity, since the present position of knowledge does not permit of this being done with accuracy. The ultimate classification will be one in which the so-called mental diseases are simply placed in their proper relationship to other diseases of the nervous system; they certainly will not collectively form a special subdivision.

ÆTIOLOGY AND PATHOGENESIS.—It is now very generally recognised that there are two great factors in the pathogenesis of a very large majority of cases of insanity—(1) an inherent weakness of individual organisation, and (2) certain exciting or determining causes. The essential nature of the inherent weakness of individual organisation which predisposes to the occurrence of insanity is as yet very imperfectly understood. That such a predisposition does, however, exist in many individuals, and that it tends to be transmitted from generation to generation, are facts too clearly proved to admit of dispute at the present day. There is conclusive experimental evidence that the nerve-cells of lower animals vary within considerable limits in different individuals of the same species in regard to their vulnerability to certain toxic agents. Extensive lesions of essentially the same character as those produced by such toxic agents in lower animals can be demonstrated in the brains of persons who have died during an attack of acute insanity, in the pathogenesis of which it is now certain that toxins play an essential part. On the other hand, there are the strongest grounds for believing that the same toxins may act

upon the nerve-cells of other persons without producing either similar lesions or corresponding symptoms. There is, therefore, reason to regard predisposition to insanity as determined by a comparatively feeble resisting power of the brain-cells to the action of certain toxins, or by an instability of cerebral tissue.

The exciting or determining causes of insanity are very variously enumerated and classified. But, with very few possible exceptions, they are all capable of being regarded as consisting in the action of toxic substances upon the cerebral tissues. These toxic substances may conveniently be classified as follows:—

(1) Those that are introduced from without, such as alcohol, morphine, lead-salts, cocaine, &c. This form of toxic action is often distinguished by the term *hetero-intoxication*.

(2) Those that are generated in the tissues of the body itself, in the course, or as a remote result, of various infective and non-infective diseases, such as syphilis, influenza, rheumatism, &c.; or in consequence of perverted functional activity of various organs such as the liver, kidneys, thyroid gland, &c.; or in association with other disorders of metabolism, such as those determined by living in bad hygienic conditions, and by various forms of mental shock and over-strain. To such toxic action the term *auto-intoxication* is commonly applied.

(3) Those that arise in the contents of the alimentary tract in consequence of functional derangements of the digestive organs, and are absorbed into the system, producing the condition generally referred to as *auto-intoxication from the gastro-intestinal canal*.

(4) Those that are developed by the action of micro-organisms which have gained admission through the alimentary tract into the blood-stream, producing the condition known as *auto-infection*.

It has long been generally recognised that certain forms of insanity are determined by hetero-intoxication. Perhaps the most obvious example of the kind is alcoholic insanity. It is only comparatively recently, however, that the vast importance of auto-intoxication as a cause of insanity has been adequately realised. As above indicated auto-intoxication has numerous different forms. In many instances it is initiated by the action of micro-organisms, that is to say, by infection, but the primary action of the specific toxins is soon reinforced, and indeed often entirely replaced by various secondary intoxications. Other forms of auto-intoxication have no special relationship to organismal infection, but arise merely from the disordered functional action of various glandular organs and tissues.

The all-important rôle of intoxications and infections in the pathogenesis of nervous diseases will, perhaps, be better understood from the following conclusions recently formulated by D'Abundo and Agostini, whose views may fairly be regarded as representing the consensus of the modern authoritative opinion upon the subject:—

(1) In the pathogenesis of nervous diseases in general, infections and intoxications are the most frequent, conspicuous, and active element, and this at all periods of life, intra- and extra-uterine.

(2) An infective-toxic heredity (e.g. syphilis, alcoholism, &c.) favours in the descendants the development of infective-toxic nervous diseases with typical lesions.

(3) Infections and intoxications in the parents,

or in the mother during gestation, very often produce in the foetus a most marked retardation in the process of myelinisation in the different systems of nervous connection.

(4) Some of the degenerative neuroses are to be regarded as due to defective cerebral and spinal organisation, arising from intra-uterine toxic pathological processes that have been cured.

(5) Infections and intoxications of the nervous system favour the development of secondary intoxications which feed, reinforce, and complicate the clinical phenomena, and together produce the forms of disease due to poly-intoxication.

(6) The action of infective-toxic agents can display itself in any part of the nervous system, leading to peripheral or central, systemic or disseminated localisation, and resulting in the acute or chronic neuro-psychoses.

(7) Mental confusion is merely the most frequent clinical type of infective-toxic action; other psychopathic types may also have a toxic origin.

(8) Acute delirium may be regarded as a clinical manifestation caused by various infective-toxic agents.

(9) Recent researches upon the ætiology of general paralysis of the insane greatly strengthen the theory of its infective-toxic origin.

(10) The clinical manifestations of infections and intoxications of the nervous system are the resultant of more or less profound nutritive disturbances, which at certain stages are capable of arrest, even when the symptomatology is such as to make us doubt the possibility of recovery.

We shall briefly indicate the probable relationship of these various forms of intoxication to some of the more important clinical varieties of insanity.

There are undoubtedly certain cases of acute insanity that are brought on by over-exertion of brain-function (idiopathic insanity). It seems very improbable that the cerebral disorder in these cases is the direct result of the excessive functional activity of the cortical neurons, because it is certain not only that these elements have great powers of recuperation after fatigue, but also that their functional activity becomes practically suspended long before an irreparable state of exhaustion is reached. The morbid cerebral changes which develop in consequence of such over-exertion of function are probably to be explained by certain secondary changes. The continuous or frequently recurring excitation or irritation of the nerve-cells induces cerebral hyperæmia, which from various causes tends to be maintained for an indefinite time; it is possible that the function of the vaso-motor nerves becomes overstrained. A chronic sub-inflammatory condition is produced; the metabolism of the nerve-cells becomes disordered; and waste products, abnormal in kind or in quality, are discharged into the cerebral lymph-channels. Hence the tissues forming the walls of these channels undergo proliferative and degenerative changes and at the same time tend to become slightly infiltrated by leucocytes. More or less serious obstruction to the passage of the lymph naturally results. The continuations of these channels in the Pacchionian villi and dura mater (the whole extent of which is now known to transmit cerebro-spinal fluid to the neighbouring veins) likewise tend to become in some degree obstructed through irritation and consequent proliferation and degeneration of the tissues forming their walls. The outflow of cerebral lymph is thus

seriously interfered with, and the nerve-cells are bathed by a fluid which is in a morbid condition, being loaded with the products of waste. Hence, especially if hyperæmia is long maintained, the nervous disorder tends to become intensified and may progress even to a fatal issue. In other cases the morbid processes gradually subside, and repair takes place.

There can be little doubt that such hyperæmia and secondary local auto-intoxication are important factors in the pathogenesis of all cases of acute insanity, and also in that of most forms of chronic insanity. But there are probably many cases of acute insanity in which the primary cause is itself of a purely toxic character. Numerous observations have been recorded of the occurrence of various micro-organisms in the blood of persons suffering from acute delirious mania. For the most part, however, these organisms have been simply the common pathogenic bacteria associated with supuration, and it is doubtful if their presence in the blood can be regarded as representing more than a secondary auto-infection. This at least is the view maintained by Ceni and Ferrari, who have very carefully investigated the whole question. There is much greater reason for the belief that the special bacillus isolated by Bianchi and Piccinino is the determining cause of one form of acute delirium, although absolute proof is still wanting. The remarkable cures that have been obtained by Marro and others by washing out the stomachs of patients suffering from acute mania, as well as other evidence bearing upon the question, would seem to indicate that many cases of this disease are determined by auto-intoxication from the gastrointestinal canal. It is also maintained by some authorities that certain cases are the result of conditions of simple auto-intoxication, arising in ways not as yet understood. The delirium frequently associated with many severe febrile diseases is plainly of toxic origin, although in such cases there is doubtless at the same time diminished resisting power on the part of the cortical nerve-cells.

Acute alcoholic insanity is clearly determined chiefly by the direct action of alcohol upon the cortical nerve-cells. In chronic alcoholic insanity we have to recognise, in addition to the same factor, a progressive secondary intoxication resulting from organic changes in various organs, more especially the kidneys, liver, and stomach. Although the precise nature of normal senile involution is at present in dispute, there can be no doubt that, in its later stages at least, senile insanity is essentially the result of auto-intoxication dependent chiefly upon organic changes in the abdominal and thoracic organs.

General paralysis of the insane is now clearly recognised to be a toxic disease. *See* GENERAL PARALYSIS OF THE INSANE.

The relation of disorders of the cerebral circulation to the different forms of insanity is certainly as yet in many respects very obscure. We are inclined to believe, however, that such disorders have much greater importance than is at present generally attributed to them, at least by neurologists in Great Britain. The comparative disregard in which they are now held as factors in the pathogenesis of insanity is doubtless largely due to the influence of the writings of Leonard Hill, who on the ground of numerous experimental observations has formulated certain

conclusions with which much of the older teaching, founded mainly upon clinical observation, is clearly incompatible. Hill maintains that the quantity of blood within the cranium is practically invariable (the Monro-Kellie doctrine), and that therefore cerebral arterial hyperæmia can only imply an increased flow of blood through the brain, not a greater distension of vessels; and that cerebral venous congestion necessarily implies compression of arterioles and capillaries, and therefore arterial anæmia. He also maintains that there is no local mechanism by which the blood-supply to the brain is regulated, and that 'the cerebral circulation is controlled by the vaso-motor centre acting on the splanchnic area.'

With regard to the first of these conclusions, it seems to us that Hill has been led into error by neglecting to take into account the displaceable lymph within the substance of the brain itself, and by failing to recognise the elasticity of the vessels and other cerebral tissues. When these factors are taken into consideration, it becomes evident that the quantity of blood within the brain is capable of undergoing important variations through inverse variations in the quantity of the lymph within the brain; and that vascular distension is not limited, as Hill maintains, by the rigid walls of the skull and the 'incompressible brain-substance,' but by the contractile and elastic coats of the vessels themselves.

With regard to the second conclusion, we maintain that Hill's experiments are by no means decisive, and that there is strong evidence in support of the existence of a local mechanism for the regulation of the cerebral blood-supply. Vaso-motor nerves in the pial arterioles have now been clearly demonstrated, and it is impossible to believe that they can have no functional importance. Moreover, prior to publication of Hill's work, Cavazzani, using methods certainly no less trustworthy, obtained experimental evidence of vaso-motor action upon the cerebral vessels, and more recently Spina has recorded similar observations. Lately, also, Acquisto and Pusateri, and D'Abundo have demonstrated at least the anatomical basis for a dural reflex, concerned with the regulation of the calibre of the pial arterioles.

Hence we maintain that both active and passive congestions, essentially similar in their nature and effects to those that occur in other organs, do occur in the brain, and that, although the subject is still invested with much obscurity, there are the strongest grounds for believing that there is a local mechanism for the regulation of the cerebral blood-supply, disorder of which is often an important factor in the pathogenesis of the various forms of insanity.

Normal mental action has clearly been proved to be accompanied by cerebral hyperæmia. We maintain that this is a true quantitative hyperæmia, and that it does not consist merely in an increased rate of blood-flow. As already indicated, functional cerebral hyperæmia is apt to pass into pathological hyperæmia, if the excitation or emotion that brings it about is unduly prolonged, and it is probable that idiopathic insanity (or the insanity which follows on the action of so-called 'moral causes,' such as grief, worry, anxiety, and prolonged study) is initiated in this way. In other forms of acute insanity, there is certainly as a rule, and probably always, similar active congestion. In senile mania,

active hyperæmia appears to affect certain areas specially, its incidence and distribution being in large part determined by organic changes in the vessel-walls. In general paralysis, there is constantly well-marked active congestion of the brain, which probably specially affects the cortex. The view, which has recently gained much credence, that in this disease there is a condition of cerebral anæmia, consequent upon venous congestion, is, we believe, entirely erroneous. True cerebral anæmia, consisting in a diminution in the quantity of blood within the brain, and not merely in retardation of the blood-flow, is probably an important factor in the pathogenesis of many cases of chronic melancholia. It has now been clearly established that states of mental excitement are in general associated with low arterial tension, and that, on the other hand, states of acute mental depression are very commonly accompanied by the opposite condition of high tension.

PATHOLOGICAL ANATOMY.—*Congenital Abnormalities of the Brain.*—Slight structural abnormalities of the brain are unquestionably far more common in the insane than in the mentally sound. They are especially frequent in cases of idiocy, congenital imbecility, and epileptic insanity. Some of the more gross congenital defects are quite incompatible with normal intellectual development, while many others have only rarely been observed in persons who were mentally sound. Some of the more important abnormalities that may be observed are the following: atypical arrangement of convolutions and sulci, microgyria, absence of the corpus callosum, imperfect separation of the cerebral hemispheres, heterotopia of the grey substance, porencephaly and microcephaly.

Focal Lesions of the Brain.—Localised gross lesions of the brain are certainly of very considerable importance in the pathogenesis of insanity. They are present in from 25 to 30 per cent. of cases examined after death. They consist chiefly of softenings of vascular origin, among which are to be included recent and old hemorrhagic, embolic, and atrophic softenings. The last, which are by far the most common, result from gradual occlusion of arterial branches and capillaries, owing to morbid changes in their walls, more especially endarteritis deformans and hyaline-fibroid degeneration. They occur especially in senile insanity and are generally multiple. They affect the cortex chiefly. Other gross lesions that may not infrequently be observed in the brains of the insane include primary and secondary tumours, tubercular and gummatous nodules, and sclerotic areas.

Morbid Conditions of the Skull.—These are essentially of two classes, namely (1) variations in form and size overstepping the limits of the normal, and (2) changes in the structure of the bones, evidenced especially by abnormalities in thickness, consistence, and histological characters.

The skulls of the insane in this country have not yet been sufficiently studied by strict craniological methods to permit of precise conclusions being formed regarding the frequency and significance of the slighter morbid conditions of the former class.

Changes in the thickness, texture, &c., of the bones of the skull are extremely common in the insane. The calvarium, as a rule, suffers more than the base. General or local thickening is exceedingly common. Statistics compiled by different observers show the condition to be present in from 25 to

50 per cent. of all cases. It is sometimes accompanied by the development of large irregular bosses, or of more or less numerous small excrescences on the inner aspect. The bone is usually at the same time condensed, but in some instances it is softened. The highest degrees of thickening occur in senile insanity, but the largest proportion of thickened crania is found in cases of general paralysis. Atrophic thinning is comparatively rare. It is observed mostly in cases of senile insanity. Osteosclerosis, or condensation of the bone, which is usually accompanied by thickening, is seen in about 30 per cent. of cases. The condition is practically a constant one in general paralysis. Osteoporosis, or general softening of the bone, occurs in about 5 per cent. of cases. It is mostly observed in the senile insane. The weight of the cranial bones is greatly increased in most cases of general paralysis, and also in many of epilepsy.

Morbid Conditions of the Dura Mater.—One of the most common morbid conditions of the dura in cases of insanity is an undue degree of adhesion to the calvarium. It is present, according to the statistics of different observers, in from 15 to 40 per cent. of cases. Senile insanity, epileptic insanity, and general paralysis furnish the largest proportion of examples. Morbid adhesion to the pia-arachnoid is comparatively rare. Thickening of the dura is exceedingly common, but is generally slight in degree and somewhat difficult to recognise. Atrophic thinning is occasionally to be observed. Bony formations, most commonly situated in the falx cerebri, but sometimes near the outer aspect of the membrane, occur with considerable frequency. In all cases of long-standing insanity, the dura mater also undergoes other chronic alterations which, for the most part, are recognisable only on microscopical examination. They consist in general or local proliferation and degeneration of the endothelial cells of the inner surface and of the walls of the perivascular canals. As already stated, such changes cause obstruction to the outflow of cerebrospinal fluid. They also, however, in chronic forms of insanity, have another important consequence, namely, obliteration of large numbers of the superficial dural capillaries by compression. Following upon the obliteration of these original vessels, new capillaries shoot out upon the surface of the dura. They tend to give way before the normal blood-pressure during the last few days of life, owing to fatty and other changes in their walls. It is in this way that most of the subdural 'false membranes,' so common in the insane, are developed. They consist essentially of blood-clot which, however, is very commonly in process of vascularisation. Other subdural false membranes are formed from blood which has escaped from a cerebral arteriole or vein. See MENINGITIS (PACHYMENINGITIS HÆMORRHAGICA INTERNA).

Morbid Conditions of the Pia-arachnoid.—The most important morbid change to which the pia-arachnoid is subject in insanity is one which manifests itself as thickening, milkiness, and opacity, accompanied generally by granularity of the surface. It is a constant condition in all cases of long standing. It is seen in its most extreme degrees in general paralysis and senile insanity. The corresponding tissue-changes consist of general hyperplasia of the connective tissues and proliferation and degeneration of the endothelial cells lining the lymph-spaces. The granulations on the surface

are composed of proliferated endothelial cells. In advanced general paralysis, there is usually, in addition, well-marked infiltration of the tissues with the leucocytes, indicating an acute inflammatory process. Whether or not, apart from such leucocytic infiltration, we regard the condition as inflammatory will depend upon what we mean by inflammation (*see* INFLAMMATION). We have already insisted upon the great importance of conditions of general toxæmia in the causation of insanity, and have explained how secondary local auto-intoxication is set up by morbid metabolism in the cerebral tissues. We believe that both of these conditions contribute to the production of the structural alterations that occur in the pia-arachnoid, dura mater, and skull. The toxins, which are added to the lymph in consequence of the altered metabolism in the brain itself, are probably, however, more important in this connection. The tissues of the pia-arachnoid, dura mater, and skull are bathed by a lymph which is in varying degrees unsuitable for their healthy nutrition. Hence they undergo the morbid alterations which we have briefly described.

Morbid Condition of the Cerebral Vessels.—The morbid changes that affect the cerebral vessels in insanity are of great importance, but are of so numerous and complicated a nature that we can do little more than name them here (*see* BRAIN, Vessels of, Diseases of). Two forms of granular yellow pigmentary deposit are very commonly to be observed in great abundance in the adventitia of the intracerebral vessels. One represents a pathological increase in the quantity of a normal constituent. It is generally of a light-yellow colour. The other, which has a reddish-yellow tint, consists of hæmorrhage, and is always indicative of antecedent hæmorrhage. Hyaline degeneration chiefly affects the adventitia. It occasionally occurs as an acute condition, but is more common in its chronic form of the hyaline-fibroid degeneration of Gull and Sutton. This change is very often a well-marked one in various forms of chronic insanity. It specially tends to implicate the capillaries of the first layer of cortex. Endarteritis deformans or atheroma occurs in its most severe form in some cases of senile insanity. Acute periarteritis occurs in the advanced stages of general paralysis. Colloid degeneration and calcification have been described, but are certainly very rare. The condition known as '*état criblé*,' consisting in the development of spaces at the side of the larger vessels in the white substance, is common in all atrophied brains, especially in those of the senile insane.

Morbid Conditions of the Neuroglia and Mesoglia. In all forms of insanity in which there is chronic irritation in the brain, or dead tissue to be replaced, the neuroglia-cells undergo hyperplasia. This condition is especially common in the outermost layer of the cortex, and in the white matter. It is generally present throughout extensive areas of the cortex in general paralysis. Localised areas of sclerosis are exceedingly common in the aged insane and in chronic alcoholic insanity. Ventricular granulations, which are almost constantly present in general paralysis and senile insanity, are essentially localised overgrowths of neuroglia.

Morbid Conditions of the Nerve-cells.—Although many points regarding the normal structure of the nerve-cell are still in dispute or undecided, the following brief description, which applies specially

to the larger cortical nerve-cells, probably fairly represents the consensus of opinion upon the subject among the best authorities at the present day. The nucleus is generally placed about the centre of the cell-body. It has a distinct limiting membrane and contains a reticulum and granules, and a rounded nucleolus, generally centrally situated. All of these constituents are acidophile in reaction, excepting from two to four small particles adhering to the nucleolus, which are basiphile: these represent the whole of the chromatin in the nerve-cell. The cell-body has various shapes, but is commonly pyramidal. It extends on the one hand into three or four long dendritic processes, the protoplasmic processes or dendrites, which, except close to the cell-body, are clothed with numerous short filiform or pyriform processes, the gemmulæ; and on the other into a single delicate smooth process, the axis-cylinder process or axon, which at some little distance from the cell-body begins to give off at right angles some finer branches, termed collaterals. The main fibre may become the axis-cylinder of a medullated fibre, or run a comparatively short course as a non-medullated fibre. It terminates in close relationship to another nerve-cell, either as a peri-dendritic or a peri-cellular arborisation. The basis of the cell-protoplasm consists of minute fibres, which for the most part course independently in the processes, but form a true reticulum round the nucleus. The fibrils of the axis-cylinder process arise from this peri-nuclear reticulum. In the cell-body the spaces of the reticulum are filled up by a homogeneous or faintly granular substance which has a strong affinity for certain dyes, such as toluidin blue, and which in preparations by certain methods appears in the form of minute aggregations, the Nissl-bodies, or chromophile elements of the nerve-cell. The bodies of the larger cells contain numerous minute channels which open on the one hand into a peri-nuclear space (bridged, however, by the fibrils, which are attached to the nucleus), and on the other upon the surface. Near the base of the cell, there is generally in the adult a small collection of a pale-yellow substance, the nerve-cell pigment. Various forms of reticula at the surface of the cell have been described by different observers, but their significance is still somewhat doubtful.

Although the neuron-theory, according to which each nerve-cell, together with its processes, forms an anatomically and physiologically separate element, has in recent years been boldly attacked, it is still maintained and defended by the great majority of authorities. It is now very generally believed that the nervous impulses are received by the dendrites (in some instances by the cell-body) and discharged by way of the axon (*law of dynamic polarisation*). It has been clearly established by recent observations that the chromophile substance is utilised during the functional activity of the cell. It has been maintained by some that the protoplasmic processes exhibit amoeboid movements, which have an important action in the breaking and making of connections with other cells, and that during sleep these processes are retracted. This theory has been strongly opposed by Lugaro, who, on the basis of a series of experimental observations of his own, has advanced another hypothesis, which seems to us to be much more credible. He maintains that only the gemmulæ exhibit contractility, and that not retraction but general expansion of

these appendages, implying multiplication of contacts and wide diffusion and consequent weakening of stimuli, is their characteristic attitude during sleep. In conditions of fatigue their contractility is greatly diminished; after rest their capacity to contract is fully restored. During psychical activity the gemmulæ undergo continuous movements of retraction and expansion, whereby contacts with the terminations of the axis-cylinder processes of other cells are broken and made.

Lugaro, who has undoubtedly done more than any other observer to advance our knowledge of the nerve-cell in normal and pathological conditions, has recently put forward another hypothesis which is of special interest in relation to the pathology of insanity. He states this hypothesis as follows: Two distinct elaborations of external impressions occur in the nervous centres, one inter-neuronic, at the terminations of the afferent fibres, and the other intra-neuronic, between the wave conveyed by the dendrites and the dynamical processes that develop in the interior of the cell-body; the first corresponds to the phenomena of consciousness or perception (*fenomeni di conoscenza*), the second to the affective states. Flechsig has lately divided the brain into sensori-motor and associative or intellectual areas, and has attributed certain special functional values to various portions of the latter. If his views upon this subject could be accepted as thoroughly established, they would form a highly important physiological basis for the explanation of many morbid phenomena exhibited by the insane. But it happens that at the present moment they are being attacked in their very foundations by several other high authorities, and therefore it is necessary for us to await the issue of the controversy before deciding whether they can be utilised in pathology or not.

The experimental pathology of the nerve-cell is now an extremely rich and elaborate department of neurological science. It may be said that two separate types of morbid change have been distinguished, namely, primary and secondary degeneration. The former results from the direct action of a toxin upon the cell, or from an equivalent disturbance of nutrition; the latter follows injury to the axon. The characters of primary degeneration differ greatly according to the toxin employed and the intensity and duration of its action. But in general the alteration consists first in disintegration and dissolution of the chromophile bodies (*chromatolysis*), then in disintegration of the achromatic fibrils, displacement and disintegration of the nucleus, and death of the whole element. If the toxic action ceases before the first stage is passed, recovery may take place. In secondary degeneration the changes represent a definite reaction which runs its course and terminates either in recovery or in the death of the cell. Chromatolysis begins around the cone of origin of the axis-cylinder process and gradually spreads to the rest of the cell; the fibrils and nucleus may subsequently be involved as in primary degeneration. There is considerable difference of opinion as to the conditions which influence the intensity of the reaction and determine death or recovery of the cell. Experimental pathology has further taught us that many of the cellular alterations which can be recognised in the human brain after death are really the result of terminal auto-intoxications and other conditions arising shortly before or even after death, and that we must, as far as possible, look behind such alterations

in order to see the true pathological picture of the disease from which the patient has suffered. Thus it has been demonstrated that hyperpyrexia of short duration, and long-continued pyrexia, can produce a general, more or less complete chromatolysis of the cortical and spinal nerve-cells. It has also been shown that slight chromatolytic changes are produced by inanition, which, however, are probably chiefly of auto-toxic origin. Anæmia and prolonged insomnia have also been demonstrated to be possible causes of chromatolytic and other changes in the cells. Experimental observations have further shown the necessity of caution in correlating various deformities of the protoplasmic prolongations and their gemmulæ with morbid phenomena in the human subject. There can be no question that pathological alterations in these appendages of the cortical nerve-cells have great importance in various forms of insanity, but the histological methods at present available do not serve to distinguish them clearly from other alterations which simulate them, and which, it has been clearly proved, may be caused by terminal auto-intoxication, *post-mortem* change, the fixing fluids themselves, as well as by other still obscure causes. Lastly, it has been shown that the nerve-cells are very rapidly affected by certain *post-mortem* alterations, which it is therefore absolutely necessary to understand and to be able to discount, in all studies in neuro-histology upon the human subject.

Primary and secondary degeneration are the only diseases of the fully developed nerve-cell as yet clearly distinguished. The various types of morbid change that may be observed may occur in either of these forms of disease. We can only enumerate the more important of them here, namely, chromatolysis, achromatolysis, intense colourability of the achromatic substance, pigmentary degeneration, fatty degeneration, vacuolation, varicose atrophy, varicose hypertrophy of the axis-cylinder process, displacement of the nucleus and homogeneous degeneration of the nucleus. The one disease of the nerve-cell which does not clearly fall within the groups of primary and secondary degeneration is developmental arrest. Various degrees of this condition can be recognised in the cerebral cortex in many cases of idiocy and congenital imbecility.

When we endeavour to apply this knowledge in the study of the morbid alterations in the nerve-cells of the human brain in cases of insanity, we are met by endless difficulties. We recognise at once that most of the changes which up to a few years ago were regarded as the basis of the morbid mental phenomena have little to do with these phenomena, being for the most part initiated during the last few days of life or after death. Even yet the definite facts that can be said to be established are very few in number. We have in addition, however, a number of 'working hypotheses' which greatly help us to visualise what is going on in the cortical nerve-cells in various forms of insanity. We shall conclude by briefly indicating some of the more important of these facts and hypotheses.

The special phenomena of the various forms of insanity depend not upon different forms of nerve-cell lesion, but upon the nature and intensity of the toxic or other condition causing the primary or secondary degeneration, the localisation of the morbid action and the special reactive qualities of the individual nervous system. In cases of acute mania and acute melancholia dying in the course of

the disease, from 25 to 50 per cent. of the cortical nerve-cells show distinct degeneration of primary type. This percentage is much in excess of that to be found in other toxic diseases in which there have not been corresponding cerebral symptoms. Moreover, the lesions are much more severe, and it can be satisfactorily proved that large numbers of the cells have disintegrated and disappeared. In cases of dementia, secondary to attacks of acute insanity, it can be shown that a considerable proportion, in some instances fully 50 per cent., of the cortical nerve-cells has entirely disappeared. In senile insanity there is a slow degeneration of the cerebral nerve-cells, for the most part of a primary character; its severity far exceeds that of the similar changes associated with normal senile involution. The lesion is essentially diffuse in its distribution, but at the same time it is generally more advanced in some areas than in others. Extensive complete destruction of cells takes place, both in association with and apart from their involvement in local softenings of vascular origin. In general paralysis there is also a diffuse degenerative change in the nerve-cells of the brain, chiefly of primary type. The morbid process is, as a rule, much more acute than in senile insanity, and the destruction of cells is greater. In chronic alcoholic insanity there is always a very considerable loss of nerve-cells, while many of those that remain present changes of a primary or secondary character. In polyneuritic psychosis and other conditions of 'primary mental confusion,' Ballet and Faure, as well as other later observers, have found secondary degenerative changes in the giant and large pyramidal nerve-cells of the cortex, comparable to those that occur in the cells of the anterior horn of the spinal cord in peripheral neuritis. In all of these forms of insanity there are, in association with the degenerative changes in the cell-bodies, extensive lesions of their prolongations, that is to say, of the medullated nerve-fibres of the brain. Severe change in the one necessarily implies corresponding alteration in the other; the two being merely parts of the same issue-element.

If we accept Lugaro's theory of the functional contractility of the gemmule, we may regard the insomnia so commonly associated with insanity as dependent upon an irritable condition of the cortical neurons, in consequence of which these minute appendages of the protoplasmic processes continue to contract in response to the slightest stimulus, instead of remaining in their position of rest. On the other hand we may conceive of stupor as dependent upon an abnormal condition of the neurons, in consequence of which the contractility of the gemmule is more or less completely abolished. The hypothesis of the distinctive functional values of the inter-neuronic and intra-neuronic elaborations, the first portion of which, it seems to us, may now be accepted as a postulate, chiefly serves to emphasise what we have long insisted upon, namely, the paramount importance of the nervous connections, or the established relations of one neuron with another. It is in virtue of such connections, elaborated throughout the years of growth and education, that the marvellous machinery of the organ of the mind is gradually put together, and it is by their dissolution that this machine breaks down, in other words, that the mental powers become disorganised. In accordance with the second portion of this hypothesis, we may conceive of states of simple mania

and melancholia as dependent upon abnormal metabolism within the substance of the nerve-cells, and can understand how they are compatible with unimpaired action of some of the purely intellectual faculties, the integrity of which is dependent upon the maintenance of the mutual relations of groups of neurons.

J. BATTY TUKE.

W. FORD ROBERTSON.

III. Developmental Insanity, strictly speaking, should include idiocy, congenital imbecility, and the greater part of epileptic insanity. But those conditions will be dealt with in separate articles.

SYMPTOMS.—The most typical and the most common developmental psychosis is unquestionably that which is liable to occur from puberty up to the age of twenty-five, and in 72 per cent. of the cases it takes the form of an attack of mania of a sharp and relapsing character, though in some cases it assumes a melancholic form. Only 32 per cent. of the cases occur between puberty and twenty-one, the remaining 68 per cent. occurring in the four years from twenty-one to twenty-five. Contrary to the common opinion, puberty and the three years following it, that is, the fourteenth, fifteenth, sixteenth, and seventeenth years, produce only 10 per cent. of the pubescent and adolescent insanity. A typical case of adolescent mania, once seen, is not soon forgotten. A young woman with a markedly insane heredity grows up till she is twenty-three without any neuroses, except that she remains long girlish and undeveloped in form. She then, without any sufficient exciting cause, exhibits for a few weeks a slight lowness of spirits, inattention and want of interest in her work and surroundings. This gradually passes off, and within another few weeks there appears a precisely opposite mental and emotional condition of liveliness and buoyancy of spirits. With this there is an unsettledness of conduct, a want of moral balance, a change of likings, a disregard of conventionalities and many unmaidenly ways exhibited before friends or strangers of the opposite sex. Sleep gets shortened, and a change of expression in face and eye is seen. This mild exaltation of cortical action soon passes into a more marked mania. The patient talks continuously and with little coherence of ideas; she sings loudly, dresses grotesquely, and becomes 'cheeky' to an outrageous degree, setting at naught parental and scholastic authority. She is boastful, offensively forward, immodest, impossible to please, and very perverse. She turns night into day, is irregular in her eating and in all her habits, is quarrelsome, blaming her guardians and companions for all her peculiarities of conduct, and is unable to get on with any one for more than a few hours at a time. Then comes a time when this 'simple mania' becomes really 'acute' in its character, and the patient screams, becomes incoherent in speech, tears her clothes, fights, and neglects the common decencies. She is then flushed in the face, and further altered in expression; her eyes are brilliant and fierce in look; and she cannot take care of herself in any way as to food or natural functions. During this time her temperature rises to 99.5° or even higher, her perspiration is offensive, and menstruation is temporarily suspended. She loses weight rapidly and soon looks haggard and exhausted. In a few weeks this acutely maniacal condition begins to abate, and is succeeded by what seems a near

approach to recovery of mental power and control, but with some confusion that may go on to stupor. Every one about her is hopeful and is intensely relieved to think the end of the attack is come. But this turns out not to be so, for about the time the next menstrual period is due the patient becomes mentally excited again, and goes through much the same sequence of symptoms as have been described. These periodic recurrences occur again and again until either a real and final recovery takes place after a year or so, or she sinks into secondary dementia—that most terrible of all mental states, where the hopes and fears of life, its joys and sorrows, its duties, capacities, and aspirations have disappeared for ever, and mind in the higher sense has died, while the bodily life may go on for many years. About 60 per cent. of the cases of adolescent mania recover, and 30 per cent. sink into dementia.

PERIODICITY.—The explanation of the remissional periodic character of the symptoms is that it is a morbid expression of the great law of generative and sexual periodicity. In the excited period there is always a strong sexual factor in the emotions, ideas, and speech, and the practice of masturbation is very common. Bouts of excessive sexual intercourse are sometimes indulged in, unsuitable marriages contracted, and sexual crimes committed during the early part of the exalted phase.

STUPOR AND MELANCHOLIA.—The symptoms in every individual case are of course not precisely on the clinical lines just sketched. We have in some cases delusions of suspicion and irritability, taking the place of the simple mania. In others the condition of confusion or complete stupor, or temporary mental obliteration, the 'acute dementia,' 'primary dementia,' 'dementia attonita,' of other writers, occurs as a developmental insanity, the patient becoming absolutely devoid of volition, standing still, not being able to speak or act, and looking as if the facial muscles were all thrown out of action, while the heart's action becomes very feeble. The pulse is weak and thready, the extremities cold and blue, chilblains forming on the hands and feet. In some cases ordinary melancholia occurs often with suicidal symptoms, and a tendency to periodicity in its incidence like the mania. In a very few cases a gradual weakness of mind occurs (*dementia præcox*).

Lesser Developmental Psychoses.—There are a series of lesser mental, volitional, moral, and 'conduct' changes, short of technical insanity, that are liable to occur in adolescents of both sexes derived from neurotic and insane stocks. These changes are often as distressing to deal with and more difficult to treat, while they are far more liable to be misunderstood than ordinary insanity. The chief of such conditions are stupidity or lethargy, asocial or anti-social state, causeless aversion to relatives or unreasonable defiance of authority, morbid egotism or delusional antipathies, visionary schemings or frothy religionism, and adolescent criminal acts, sexual perversions being common, as might have been expected. 'Mad' adventures, insane idealisms, and unhealthy attempts to produce original forms of literature or poetry are common enough among educated neurotics at this age. The absence of balance, common sense, practical or possible aims in life, and sobriety of conduct or thought generally is characteristic of such people, many of whom thus

show that they are true 'degenerates.' The writer regards all such as examples of the evolution of the impulse of reproduction—that organic instinct which is only second to the love of life in importance—upsetting the cortical condition and working of brains strongly predisposed to insanity or to the higher neuroses through heredity.

TREATMENT.—The most successful treatment is founded on physiological considerations. Feed well with all sorts of non-stimulating diet, such as eggs, farinaceous and fatty diet, and fruits. Give custards made of milk and eggs in large quantities. Exercise, work and amusements in the fresh air, and cold bathing are essential. The writer has no sort of belief in the treatment by confinement to bed lately recommended by some authors for such disorders. Cod-liver oil, maltine, and the hypophosphites are most useful. If sedatives are used a judicious mixture of the bromides and sulphonal (Potas. Bromid. gr. xv. and Sulphonal gr. x. three times a day) will be found useful. When patients begin to gain weight they are commonly safe—except those who are getting demented. About 60 per cent. recover. Recovery is accompanied, in addition to a gain in weight and fatness, by an expansion of the form and of the mammæ in women, and by the usual signs of completed physiological manhood in the other sex, such as the full growth of the sexual hair and beard. Many of the cases of adolescent mania relapse afterwards through child-bearing, moral upsets, alcohol, or senility.

T. S. CLOUSTON.

IV. Insanity of Pregnancy, the Puerperal Period, and Lactation.

1. Insanity of Pregnancy.—Insanity of pregnancy is rare, and accounts for about 1 per cent. of women admitted to asylums. The cases may be considered in two groups: (1) those occurring in the early months, associated with general disturbance of the circulation and nutrition, and (2) those occurring during the later months, associated with the increasing worry and discomforts of advancing pregnancy. In the first group the disorder may pass off with gradual adaptation of the nervous system to the altered conditions; while in the second the insanity is likely to continue after confinement as a puerperal insanity.

CAUSES.—(1) Inheritance of neuroses or insanity; (2) previous attacks of mental disorder, either before marriage or in connection with some previous pregnancy or confinement; (3) a first pregnancy, especially if associated with much vomiting, neuralgia, or sleeplessness; (4) moral causes, such as illegitimacy or desertion by the husband; (5) cardiac, renal, or other organic disease; (6) alcoholism or other toxic state; (7) early general paralysis of the insane.

FORM OF MENTAL DISORDER.—Most commonly the disorder is of the melancholic or stuporous type, but maniacal excitement is not rare. In the melancholic forms there may be apathy, loss of energy, and inability to fulfil ordinary duties, with self-accusation and suicidal desire, on the one hand, or agitation with hypochondriacal misinterpretation of the discomforts of pregnancy on the other. Hallucinations may be present, and suspicions of poisoning may lead to refusal of food. Aversion to the husband or to others may lead to violent assaults. Maniacal excitement may be of the delirious, the hysterical, or the ordinary acute maniacal type.

Occasionally chronic delusional insanity arises during pregnancy, and in a few cases the patient becomes weak-minded without any marked acute psychosis, and remains demented even in a first pregnancy.

PROGNOSIS.—This is, on the whole, good, especially in the early months, if the patient be removed from home and treated by rest till the nervous system has adapted itself to the new conditions. In cases occurring in the later months recovery does not take place till after confinement. The prognosis as to the mental life of the child is not a favourable one, and congenital mental defect or nervous instability is likely to result.

TREATMENT.—In mild cases rest under skilled nursing, with liberal feeding, removal from all household worries, attention to the bowels and sleep, and administration of tonics may effect recovery. In severe cases treatment in an asylum is necessary. In the administration of drugs regard must be had to the possible effect on the nervous system of the child. Induction of premature labour does not seem justifiable in the early months, as the disorder may pass off quickly; and as in cases occurring later delivery at the natural term does not cut the disorder short, there is no reason to suppose its artificial production would be beneficial, while it would add an additional risk to life.

2. Puerperal Insanity.—Insanity following childbirth is found in between 5 and 6 per cent. of the women admitted to asylums. Many of the milder and shorter cases of this nature never reach the wards of an asylum, but are successfully treated elsewhere.

CAUSES.—(1) An inheritance of neuroses or insanity. Some observers place this as high as 50 per cent. In many cases puerperal insanity is the expression of the presence of the neuropathic diathesis, and its subjects are 'degenerates' whose nervous system gives way first at the puerperal epoch. Occasionally a mother and her daughter may each suffer from puerperal insanity. (2) A first confinement, especially towards the end of the reproductive period, when the pelvis and soft parts have become unyielding. (3) Some complication attending labour, such as the use of forceps or anaesthetics, delayed labour, *post-partum* hemorrhage, ruptured perinaeum, or any cause leading to septic poisoning. The latter may be slight or severe. In some cases no doubt the mental disorder is of the nature of a toxic delirium, while in others it precedes or is merely concurrent with septic absorption, and might have occurred independently of it. Although primiparae are more likely than others to sustain injuries during parturition, the cases of puerperal insanity in which there was the most severe septicæmia were, in my experience, not primiparae. (4) Moral causes. These may be present in many cases, even where there is no inheritance of insanity and no evidence of septic complications. Any great strain or anxiety or emotional shock may upset the balance at a time when the nervous system has passed through the stress of delivery, and should have the opportunity for rest and recuperation. The birth of an illegitimate child, the death of a near relative, of the husband, or of the child, sudden fright, the apprehension of the pains and perils of confinement, excitement from officious and gossiping visitors, desertion or ill-treatment by a brutal husband, or the worry of an inefficient nurse may, for example, act in this

way. (5) Previous attacks of insanity either before marriage, or after former confinements. (6) Conditions leading to maternal ill-health during pregnancy, defective general nutrition, nervous exhaustion from frequent child-bearing or prolonged lactation, organic diseases, or alcoholism.

ONSET.—In some cases insanity has existed before confinement, and continues subsequently. In other cases it may begin immediately after delivery, and in a still larger proportion during some part of the first week. Other cases begin at varying periods up to six weeks or two months after parturition. The line drawn between the later puerperal insanity and the insanity of lactation is quite an arbitrary one, and there are many cases to which the term 'puerpero-lactational' might be applied.

FORMS OF MENTAL DISORDER.—In the main the cases fall within the two great groups of maniacal excitement and melancholic depression. Of those occurring within the first fortnight after delivery, the great majority are delirious or maniacal, while those occurring later are chiefly, but not exclusively, melancholic. A transient frenzy of excitement or delirium may occur during delivery, or immediately after, and may pass off very quickly. The mental disorder at this period is marked by its sudden onset, its extreme uncontrollable violence, its transitoriness, and the profound affection of consciousness which may be associated with an impulsive homicidal or suicidal act. Again, within the first few days after delivery a short, but very acute, delirium with rise of temperature, great restlessness and violence, hallucinations, rambling incoherence, and profound affection of consciousness may occur. Memory of the attack may be entirely lost. Transitory cases of this nature do not necessarily find their way into asylums.

Of cases of longer duration there are several varieties. Puerperal Mania is the commonest form. Within a few days after delivery there is sleeplessness, slight depression, loss of interest in the child, querulousness, and dislike to the husband and nurse. Maniacal excitement then rapidly supervenes. The cheeks become flushed, the eyes bright, the pupils dilated, the tongue dry, the pulse rapid and soft, and the temperature slightly raised. The excitement increases with noisiness, shouting, singing, and incoherent conversation which is often obscene. There is constant restlessness with struggling, fighting, and a tendency to strip off clothes, to impulsively strike those about her or the child, or even to injure herself. Relatives may not be identified, the attention cannot be arrested, and consciousness is profoundly affected. Hallucinations and delusions are frequent, and judgment is entirely at fault. Food is commonly refused, and there is loss of control over the bladder and rectum. Sleep is either entirely absent, or comes in short snatches from which the patient wakes to continue her ravings. The urine may be temporarily albuminous, or may in some cases contain sugar. The milk may be suppressed or may be secreted so plentifully that the breasts become tense and painful, abscess ultimately forming. The lochial discharge may be normal, absent, or offensive. The excitement may last a few days, weeks, or months, and is apt to recur periodically. After a time it may be replaced by depression with agitation, delusions of perdition, self-accusation, and suicidal attempts; or by stupor, silence, and apathy, but with eventual recovery, as the phy-

sical health is re-established. Menstruation is absent during the attack, and there may be a long period of delayed convalescence with amenorrhœa, eroticism, and impulsiveness.

A second variety is the Acute Delirious type. In such cases the confusion and loss of orientation may become extreme, and there is constant delirious chatter with sleeplessness, dry brown tongue, rapid and feeble pulse, and tendency to pass into the typhoid state with fatal result. In these cases the temperature is irregularly raised, not infrequently with rigors, offensive lochia, pelvic inflammation, abscess in the breast, pulmonary congestion or consolidation. In a third group the excitement is more of the Hysterical type with eroticism and less profound loss of consciousness. The fourth variety is acute Confusional Insanity, occurring chiefly in patients who have been much exhausted at confinement or have been in a low state of health previously. There is dreamy confusion, inability to answer questions or to grasp the environment, hallucinations, restlessness without excitement, aimless wandering about, refusal of food from inability to grasp its nature, and general resistance. Delusions are not as a rule marked. There is loss of control over the emunctories. These cases improve rapidly with treatment, but if neglected may pass, on the one hand, into a low delirious state, or into stupor and dementia.

Puerperal Melancholia may begin almost immediately after delivery, but most commonly more than a fortnight after. The depression may be of the religious type, with self-accusation of crimes or wickedness and delusions of perdition. Complaint of being 'unworthy,' or of having lost natural affection, or of having brought ruin on the family, is common. Occasionally the depression is hypochondriacal in type, with delusions about the pelvic viscera of being 'unnatural' or of being 'not human.' In another group there is terror at imaginary impending harm, dread of arrest, or fear lest the child be starved or injured. Delusions as to the child's health, such as that it is deformed or black, may lead to intense disgust with it and infanticide. In other cases there is great depression with apathy, loss of interest, and stupor. There may be either silence and downcast expression with loss of energy, or, on the other hand, restless agitation with constant noisy bewailing. In all these cases there is great risk of suicide, and frequent attempts are made. Sleeplessness, refusal of food, and personal neglect are constant, as are also amenorrhœa and cessation of the secretion of milk.

Chronic delusional insanity with organised ideas of persecution may originate in the puerperal state, the prognosis being then very unfavourable. In rare cases General Paralysis begins at this period.

PROGNOSIS.—About 80 per cent. of cases recover. Acute cases often recover quickly, and most of the maniacal cases are convalescent within 3 or 6 months. Patients suffering from melancholia are not placed under care as early as those with excitement, unless suicidal or homicidal symptoms appear early, and therefore take longer to recover. The prognosis is favourable so long as there is amenorrhœa and imperfect restoration of the general health, but bad when menstruation has been re-established and the general health restored without corresponding mental improvement. Death may occur in septic or acutely delirious cases or where prolonged maniacal excitement has led to exhaustion; although

some of the most severe cases with septic complications recover perfectly if treatment is undertaken promptly. The prognosis in the event of further confinements is commonly unfavourable, some women becoming insane after each labour.

TREATMENT.—Rest in bed during the early stages is of the utmost importance. Perfect quiet and freedom from all suggestion of home-worries are essential. The patient must be removed from home; or, if this is not feasible, the husband and child must be removed, and the patient herself efficiently nursed. The child should be at once weaned, and never, on any consideration, be left in the patient's care. She may neglect it so that it dies, or may kill it accidentally in excitement, or as the result of delusions or hallucinations, or in a sudden impulse. If left alone she may even destroy herself during maniacal excitement, without any previous indication of suicidal tendency. The physical state must be carefully ascertained, especially the condition of the uterus, the lochia, the breasts, and the temperature; for the possibility of septic absorption must not be overlooked. In the cases beginning early after confinement the uterus or vagina should be washed out, but in the later cases this is not necessary unless there is evidence of local disease. The patient must be fed liberally. If solid food is refused or inadvisable, abundant liquid food must be administered—if necessary, by the nasal or œsophageal tube (*see* FORCIBLE FEEDING). The bowels must be regulated; a brisk purge at the onset is often beneficial. In cases of profound exhaustion or delirious excitement stimulants are needed. Sleeplessness must be treated as in other cases of acute mental disorder, but food is more important than narcotics. The milder and transitory cases may be treated out of an asylum, but in all severe cases such care is necessary, and the earlier the patient is put under control, the earlier is recovery likely to follow. During convalescence tonics and emmenagogues are useful. The amenorrhœa, however, usually passes off as the general health improves. After recovery a period of complete rest is needed, and the risk of pregnancy should be avoided.

3. Insanity of Lactation.—It has been pointed out (*see* PUERPERAL INSANITY) that the borderline between puerperal and lactational insanity is an artificial one, and is usually fixed at six weeks or two months after confinement. It is, however, impossible to say that mental disorder, becoming evident three months after delivery and when lactation has become established, is not due in some measure to the remote effects of child-birth. In cases occurring in the earlier months of lactation both factors have to be borne in mind, while in those occurring later the exhausting effect of prolonged lactation is the principal exciting cause.

CAUSES.—(1) Inheritance of neuroses or of insanity; (2) Previous attacks of mental disorder, especially puerperal or lactational; (3) Defective general nutrition, as in women of the poorer classes, exhausted by frequent child-bearing and prolonged suckling.

FORMS OF MENTAL DISORDER.—The onset is generally gradual. At the beginning there is neurasthenia with vertical headache, sense of fatigue, loss of flesh, loss of energy, sleeplessness, anæmia, and constipation. Mental depression supervenes and soon passes into well-marked melancholia. In the experience of the writer, this is the

predominant form of disorder; but in many cases the depression is followed by maniacal excitement. This sequence is partly a matter of idiosyncrasy, and partly dependent on the amount of bodily exhaustion which is always present in these cases.

Melancholia from lactation is commonly marked by self-accusation of wickedness or neglect, dread of being 'lost' or ruined, and strong determination to commit suicide. The mother who dreads a horrible future may kill her child and herself to escape from its possibilities. One patient of the writer's heard voices, saying to her 'Why don't you kill the baby and your husband?' Hallucinations of the senses, especially of hearing, are common, and may influence the conduct. In some cases there is stupor with absolute refusal of food and impulsive suicidal attempts; in others, agitation and resistance to all attention.

Maniacal excitement is of the ordinary acute maniacal type with violence, destructiveness, confusion of thought, and incoherence. The acute delirious type is uncommon, and there is rarely a rise of temperature.

In a small proportion of cases chronic delusional insanity begins during lactation, and dementia may result, especially where there has been a long period of treatment at home, or the child has still been nursed long after exhaustion has set in.

The milk may cease to be secreted before or at the time of the onset of depression. Amenorrhœa is common in lactational insanity, and is dependent on the co-existing anæmia.

PROGNOSIS.—Recovery takes place in 75 to 80 per cent. of cases. There is much less danger to life than in puerperal cases, but the possibility of suicide must not be overlooked.

TREATMENT.—Anæmia and malnutrition being constant symptoms, tonics are needed in most cases as well as abundant feeding. In cases of melancholia especial attention must be directed to the bowels. Narcotics should, if possible, be avoided, and chloral hydrate and sulphonal should rarely be used. Sleep is more likely to follow gentle exercise, feeding at night, and the judicious use of stimulants. The immediate cessation of the exhausting drain of lactation is imperative, and the patient must be separated from her husband and child lest she kill them. The extremely suicidal nature of the melancholic cases renders treatment in an asylum almost always necessary; and this procedure is equally advisable in maniacal cases, as the form of the disorder never disappears rapidly, as happens in some puerperal cases.

R. PERCY SMITH.

V. Senile Insanity.—Senile mental decay is most likely to occur in persons of neurotic or insane stock, and to be accelerated in its onset by constant undue stress of work, or by the effects of alcohol, syphilis, or head-injury. In the great majority of cases the period from 60 to 65 years is that in which it first appears. In women the mental disorders of the climacteric, sometimes ending in dementia, mark the period of involution as occurring somewhat earlier than in men.

Insanity may occur in old age, and yet not be true senile insanity. Recurrent insanity dating from the period of adolescence may continue to recur in old age with intervals of comparative health, and recovery from such attacks may occur even in old age. In other cases senile decay may

be the immediate cause of mental disorder in patients who have suffered from insanity at other epochs or crises, as, for example, after parturition or at the climacteric. Previous mental disorder may have occurred in this way as much as thirty or forty years before, the patient having recovered and remained well till the onset of senility. Mental disorder is also met with in old age in association with cerebral lesions due to occlusion or rupture of blood-vessels, or in uræmia and other toxic states. It is impossible to distinguish from senile insanity all those cases due to some organic cerebral change, since the essential feature in senile decay is gradual failure of brain-nutrition with wasting and degeneration of its substance in association with rigidity of arteries and impoverished cerebral blood-supply. The term 'senile insanity' should, however, be limited as far as possible to mental disorders occurring for the first time in old age apart from gross cerebral lesions. Dementia is not by any means the only form of disorder met with at this epoch. Senile insanity is often erroneously spoken of as due to 'softening of the brain' and as being always incurable. There are, however, functional mental disorders in old age from which the patient may recover, as well as others dependent on permanent atrophic changes which end in dementia. The various forms will now be considered.

1. Melancholia.—Mental depression in old age may be the precursor of dementia, the initial stage of a maniacal attack, or the commencement of a definite melancholia. The earliest symptoms are generally those of fatigue or exhaustion. Loss of vigour and lack of application to the usual occupation is experienced, everything becomes a burden, thought is attended by painful effort, and attention cannot be concentrated or sustained. Sleeplessness and continuous anxiety concerning the trivial details of daily life follow, accompanied by loss of appetite, distaste for food, dyspepsia, constipation, and loss of flesh. The patient becomes irritable, especially in the home-circle, and, though needing rest, is unable or unwilling to cease from work. He accuses himself of being lazy, and tries to force himself to do more. Injudicious friends tell him it is 'nothing,' and advise him not to give way. He has noises in the head or headache, dreads impending evil, doubts his conduct or motives, and shows indecision and forgetfulness, loss of interest, increasing gloominess, and thinks of suicide. The disorder may remain as a 'simple melancholia,' passing off with rest, removal of the causes of stress, and treatment directed to the restoration of general health. In more severe cases delusions of wickedness, of being an unpardoned sinner or murderer, or of having caused disaster to his relatives or the whole world, are present. Long past sins, errors, or sexual irregularities are dwelt on, and their importance exaggerated. The attention fails, no work is possible, and either there is silence and complete lack of energy, or agitation and loud lamentations as to his state. Delusions of possession by the devil, and hallucinations of hearing and of other senses are common. The memory may not be markedly affected, but as a result of loss of attention recent events are not recorded as in health. Such patients may be able to give a clear account of their financial or domestic relationships though unable to direct their affairs. Sleep is always much disturbed, and the depression and agitation are worse at night or in the early morning.

Suicidal desire and attempts are very common, food is often refused, and there is neglect of personal cleanliness or of tidiness in dress. The patient wastes, his tongue is foul, his bowels confined, and his pulse hard and tense. In other cases, the delusions concern mainly the patient's financial and social position rather than his moral condition. He believes he is ruined and has dragged all his family with him, that he owes money which he can never repay, that he is a fraudulent bankrupt, that he has 'no money and no clothes' in spite of ocular demonstration to the contrary. Desire for death is common, and sometimes there is a wish to kill those dependent on him in order to relieve them of the impending ruin. Food is refused because it cannot be paid for.

Hypochondriacal melancholia is also common in old age. The patient may believe he is decomposing and giving rise to offensive vapours, or that he is dying or dead; or his complaints may be limited to the state of his brain, his viscera, or his sexual organs. He may feel that his brain is split or separated from the cord, that it is 'sobbing and moaning' or that there is a 'roaring pain' in it. There may be a feeling of suffocation or delusion that the heart has 'gone.' The abdominal viscera may seem diseased, the food 'will not pass,' there is 'no inside,' the bowels are 'lost' or 'completely obstructed.' Patients with delusions of intestinal obstruction are extremely suicidal and obstinately refuse food. The diminution of sexual power and desire associated with old age may be looked upon as a 'terrible disaster;' and there may be delusions as to the size, structure, and form of his penis, testes, urethra, or bladder. Such patients are often extremely suicidal and prefer death to the thought that they may have lost sexual power. Hypochondriacal melancholia is much less curable in old age than the before-mentioned form. In some cases the grouping of ideas of depression is not strictly limited to one variety, but, for example, hypochondriacal ideas are combined with delusions of perdition or ruin. In other cases depression is associated with suspicion of the motives of others, delusions of unfaithfulness, irritability, querulousness, and hostility. Such patients are likely to develop fixed delusions of persecution.

2. Delusional Insanity (Senile Paranoia).—This may occur primarily in old age and may exist in the depressed or exalted form, the latter being the less common. Delusions of persecution may develop slowly without marked depression, with ill-defined dread of injury to prospects, position, family or life, commonly with hallucinations of hearing. In old women delusions of sexual persecution may arise in association with vulgar or vaginal irritation. There may be belief that rape is attempted at night, or that plots are laid against the patient's chastity. With this there may be delusions of being drugged or chloroformed, of being watched through holes in the wall or through floors, of being X-rayed or of having electric shocks. The prognosis in these cases is very unfavourable.

3. Mania.—Mania may occur in old age as a functional disorder and be recovered from, or it may be the forerunner of senile dementia, or be associated with organic disease of the brain. Usually there is a short period of depression with sleeplessness and then gradually increasing irritability, outbursts of violent temper, resentment of opposition, eroticism, exalted self-feeling, and moral perversion.

In this state there may be sexual crimes subjecting the patient to criminal prosecution, or merely lasciviousness, obscene conversation and acts. Offers of marriage may be made to young girls or to designing women. The exaltation may show itself in impossible schemes for making money, and as a result of opposition to unreasonable schemes or expenditure. The patient may alter his will and leave his property to those who have no claim to it. There is vacillation, indecision, impulsive violence, confusion of thought, and lapses of memory. There is often great difficulty in treating a patient in this state, as the disorder may remain as 'simple mania,' and it may be very difficult to certify him as insane. With enforced rest and care, however, this condition may pass off, or it may recur, or pass into more definite 'acute mania' with excitement, noisiness, violence, destructiveness, incoherence, exalted delusions as to wealth, strength, and prospects, and dirty habits. Occasionally the disorder is of the confusional type, and in others extreme delirious excitement with complete loss of orientation, rise of temperature, and profound exhaustion ends rapidly in death. In all cases of senile mania the memory is more or less affected, in some only as a loss for the events of the attack, in others, especially those in whom the disease comes on in later years, it is permanently affected for both recent and remote events. There is far more risk to life, and danger of permanent damage to mind, in senile mania than in senile melancholia, especially in cases with marked arterial or cardiac degeneration, chronic renal disease, or gross cerebral disease. Senile mania may be recovered from, but there is almost always inability to resume business, and if there be not loss or weakening of memory there may be emotional instability, irritability, and perhaps loss of moral sense.

4. Dementia.—Dementia may arise primarily or be preceded by functional mental disorder. Its development may be spread over many years, mind and body failing together, or, in the course of a few weeks, it may end in profound decay of mind, general weakness, failure of nutrition, and death either from general asthenia or some local complication such as cerebral hæmorrhage or thrombosis, pulmonary hypostasis and pneumonia, cardiac failure, cystitis, or diarrhoea. In some the memory fails gradually, the patient passing comfortably into dotage, needing constant care but giving no trouble; while in others there is so much disturbance of conduct that constant restlessness, childishness, loss of sense of decency, impatience of control, and attempts to transact business for which there is no mental power, render care in an asylum not only advisable but necessary. The emotions are blunted, or if there is a momentary disturbance the effect passes away as the cause is forgotten. Hallucinations are rare in uncomplicated senile dementia.

The greatest failure is shown in the intellectual faculties. The memory for recent events is especially affected. Daily events make no impression, or are forgotten in a few hours or days. Localities or individuals make no impression, the patient sometimes not recognising his own family or house, nor even remembering his name, the names or number of his children, the extent of his means, and the people who ought to benefit by his will. All conception of time is lost, and those long dead are spoken of as if alive. Habits of cleanliness disappear, the patient perhaps exposing himself

almost unconsciously, or passing urine or feces in his clothes or in public, or indulging, apparently intentionally, in filthy habits. He may be easily led, and give away his money or sign documents at the instance of unscrupulous people, or may, on the contrary, be querulous, obstinate, and self-willed. Sleep is often disturbed by nocturnal restlessness or talking, and by a desire to get up. The appetite is usually good, the patient taking childish pleasure in his food. The handwriting may merely show senile tremor, or be absolutely unintelligible; it often gives evidence of the great loss of memory. Although sexual power is much diminished or lost, there is often in the early stage increased sexual desire.

The progressive nervous degeneration is shown by tremulousness, feebleness of grasp, and unsteadiness of gait, with eventual loss of power of walking even without definite paralysis. Eventually the patient becomes bedridden, his sphincters cease to act, swallowing becomes more difficult, general wasting is marked, the heart becomes feeble, and convulsive seizures may occur and close the scene.

In some cases the symptoms simulate general paralysis, but there is less tendency to loss of pupillary light-reflex, less characteristic affection of speech and handwriting, and greater liability to hemiplegia, than in that disease. True general paralysis may, however, occur in old age.

PATHOLOGY.—There is general wasting of the brain-substance with increase of subarachnoid fluid compensatory to the wasting. To the naked eye the cortex appears thin, pale or yellowish, and has lost its characteristic striation. Arterial changes are always marked. Extreme atheroma of the larger cerebral vessels, as also military aneurysms, are often found, as well as hæmorrhages and thrombosis. Microscopically there is seen to be extensive arterio-sclerosis or hyaline-fibroid degeneration. The neurons show degenerative changes of the primary type very widely spread, and in advanced cases some of them may have disappeared. There is also hypertrophy of the neuroglia throughout the cortex, and especially in the neighbourhood of the degenerated nerve-cells. Even if there be no previous evidence of a large hæmorrhage or patch of softening, the microscope will often reveal small extravasations and minute areas of softening. The dura-mater is often adherent to the calvarium and may show hæmatoma (*see* PACHYMENINGITIS HÆMORRHAGICA) on its inner surface. The pia-arachnoid is thick, milky, and opaque in patches, but strips readily from the convolutions. Degenerative changes are commonly found in other organs, especially the heart and kidneys.

TREATMENT.—Many of the milder cases of senile dementia can of course be treated at home if the means permit. The patient should at first be kept in bed so as to secure as much rest as possible and avoid further exhaustion of strength, and to relieve arterial tension and permit of the treatment of any local or general disease. Treatment must be directed to the elimination of any toxins, such, for example, as are associated with constipation, uræmia, excess in nitrogenous diet, or in alcohol, and to the complete cessation of mental work. The diet must be light, but nourishing and abundant. Regard must always be had to the question of testamentary capacity.

R. PERCY SMITH.

VI. Delusional Insanity.—**SYNON.** : Monomania, Paranoia.—The terms at the head of this section comprehend abnormal mental conditions which have puzzled every student of mental medicine. It is not every insane person suffering from delusions that can be described as suffering from delusional insanity. Persons so affected are either those who have sense-perceptions different from the sane, and most varied in their manifestations; or those who have fixed ideas which are not removed by argument, and which generally have some direct relationship to the preservation of the individual himself, or his environmental existence in society. Essentially the condition is chronic, and restricted to a fixed delusion upon one subject, but it is erroneous to think that the victim is of sound judgment and healthy feeling on all others. If there be one symptom which is characteristic of this condition, it is the presence of hallucinations—sense-impressions not excited by external stimuli—and mostly those of hearing. Together with sense-impressions wrongly interpreted (illusions) they combine to develop and form all possible varieties of delusions, and although delusions connote an impairment of the highest faculty of reason, in these cases there is generally no marked mental weakness. On the contrary there is much shrewdness and pertinacity, volition is strong, and the emotions are well under control, but during a considerable part of the progress of the disease, the patient is necessarily a source of considerable danger to himself and others. Much of the violence and homicide which is perpetrated by the insane before legal restraint is imposed is caused by this class, an important factor from the medico-legal point of view.

We prefer the title Delusional Insanity to its synonyms, since it gives us the most important characteristic fact established by actual observation. Monomania was the term applied to this form of mental aberration by Esquirol, who considered it to be in the main an exaltation; when the fixed delusion was accompanied with depression, he gave it the title of ‘lypomania,’ thus confusing it with some forms of melancholia. English alienists have mostly preferred Delusional Insanity, while Paranoia (*παρά, beyond; and νόσος, to understand*) has been accepted by continental authorities in Europe and America. The term Paranoia has been applied generally to all chronic cases of insanity, whether primary or secondary; and it has been made to include all borderland cases, eccentrics, cranks, grumblers, letter-writers, and crazy persons of all sorts, more especially those who avow their belief in symbolism and allegorical expressions and figures. Persons evincing unfounded and unreasonable credulity, those who believe in fetichism and who embrace mystic and occult dogmas have been brought into the same class, the reason being that an anachronism is looked upon as a morbid character; that a belief in alchemy, or in the power of magnetism and electricity, which was compatible with high intellectual ability several centuries back, is now a sign of atavistic degeneracy; that the acts of chronic lunatics are reversions to earlier conditions of the human race; and that the delusions of persecution so frequent in this class are a survival of struggles for existence which were necessary in ancestral days and lawless times, but which are now only an indication of perversion and degeneration. The real nature of the conditions included

in the term 'paranoia' is much disputed. Mickle states that all cases do not belong to the great group of hereditary neuroses. He describes the following divisions of paranoia: A, Depressed—(a) persecutory, (b) hypochondriacal, (c) querulous; B, Expansive—(a) ambitious, (b) religious, (c) erotic. Our own opinion is that this form—for which the term 'paranoia' should not be used—is of all others that in which heredity plays the chief part, having a tendency to make the disease apparent during one or other of the somatic crises through which the life of an individual proceeds, e.g. childhood, puberty, adolescence, the puerperal, climacteric, or senile epoch, there being a constitutional tendency to mental disorder of a delusional type. Although there is less emotional disturbance in this form than in any other variety of insanity, it is incorrect to state that there is none; for every action and every thought has a distinct fundamental feeling-tone of pleasure or pain, and the egoistic feelings which so predominate in these cases obtain such an ascendancy over the intellectual life that the personality becomes completely changed.

Having advocated the term Delusional Insanity, we include in this class all those who suffer from a chronic form of insanity, whether hereditary or acquired, whose delusions—dominating the whole mind—appear to be fixed and systematised, and in whom there is not the characteristic emotional exaltation of mania nor the self-depreciation of melancholia.

In the *hereditary form*, the delusions may occur at an early age, or at any period of life, and may evolve into a transformation of the intellect, the will, or the emotions and sensations. It is this group which gives rise to the so-called monomanias of the various faculties, impulses, and obsessions. Not infrequently there is among this class considerable eccentricity or ability amounting even to genius, or there may be flagrant moral depravity and a total lack of ethical feeling. In these cases the delusions may be polymorphic, but there is, as a rule, a freedom from hallucinations, and many make temporary recoveries.

In the *acquired form*, which is less common, the disease manifests itself during the best period of adult life (35–45). The manifestation is preceded by a period of incubation, lasting possibly for years, during which there is a morbid timidity, hesitancy, and uncertainty, and the onset is rarely abrupt; for there are no psychical or physical stigmata, and usually no impulses or obsessions. The delusions are systematised and the consciousness is confused and obscured through the multiplicity of the hallucinations, the patient explaining these as due to external intervention. The disease is chronic and progressive, but there may be lucid intervals, during which the person may infect his friends, or, not infrequently in asylums, those about him, upon whom he is able to impose his personality—*délire double*. The termination is generally a slightly marked dementia.

The varieties of delusional insanity are characterised in the main by either: (1) exaltation, or (2) ideas of persecution, and the delusions are based upon hallucinations or illusions of the senses. The hallucinations have been regarded as having their situation in the cortical centres, and are possibly due to an abnormal erethism of the cortex, and automatic excitation under unnatural conditions giving rise to a nervous discharge as if provoked by a peripheral

impression. The senses affected are usually the auditory, not infrequently also the visual and tactile—those upon which the most highly differentiated experiences depend, being the most used and most markedly evolved of the senses. This excitation reacts upon the higher psychical centres with all the reality of normal sensation, giving rise to painful delusions. Occasionally also the converse is true, and the hallucination is awakened in the perception-centre through the influence of a higher psychical region, so that the idea or a thought may awaken in a sensory centre a representative symbol, such, for example, as an auditory verbal image, followed afterwards by hallucinations of hearing. It frequently happens that patients will complain of humming, buzzing, or complex sounds, before the actual words develop, and one of the most common explanations offered by those affected when projecting these sensations outwardly, is that 'they' speak so low, or make sounds which are indistinct, coming from above or below, by day or by night. An 'echo' is often complained of by patients, 'their thoughts are being read and reverberated like an echo'; and acts committed by them are believed to be auditorily described and reproduced. A patient informs me that it is useless his writing to me, as what he writes is immediately repeated by 'them' and precipitated into my presence before his own statement is finished. While reading the newspaper one patient is accosted by unfriendly voices, and a duologue results between the voices (auditory lobe, lower centre) and herself (frontal lobe, higher centre). Sometimes the sensations may appear as internal voices, excitation of the auditory centre being propagated to the motor word-centre in physiological connection with it, giving rise to *motor verbal* or *psychic hallucinations*, the patient feeling the words being uttered in her own throat and mouth.

Sensory disturbances are not uncommon, and patients may be seen with weary persistence almost the whole day brushing off imaginary filth, fanning themselves from chemicals, or covering different parts of their bodies from powders, or objectionable liquids which are being thrown, blown, or flicked at and over them, to their intense annoyance and disgust, and always, so far as they know, without cause. Olfactory and gustatory hallucinations are infrequent. The unusual experience and secret character of these all-powerful and unceasing annoyances cause them to be explained by the immediate power of great natural forces, such as magnetism, electricity, waves of matter, hypnotism, telephones, and microbes, and to be carried out by powerful unrecognised agencies, such as devils, anarchists, murderers, witches, freemasons, &c. The patient (whose personality becomes completely altered, owing to these newly recurring sensory troubles and false ideas, contributed by the different morbid senses to consciousness) changes from passive self-defence, during which he endured his tormentors in silence, to active hostility (persecuted persecutors). It is at this period, and probably before legal restraint has been enforced, that the sufferer carries about his person lethal weapons, which he may use criminally against inoffensive persons; and it is at this stage that the reason, led by the influence of hallucinations of the senses, deduces both sensible and improbable conclusions side by side (partial insanity). It is not surprising that irritation from an unceasing round of imaginary outrages should cause

these unhappy persons frequently to change their environment (migrating mania of Foville), to write to conspicuous personages, or commit crimes to 'invoke justice.' Not surprising is it either that the victims of this form of insanity should occasionally end their miserable lives by suicide. A patient, a literary man under the delusion of continuous persecution, moved to a solitary spot on the bank of the Medway, whence again he moved to London, and in the middle of the night clambered along the parapet of his hotel, entering an adjoining house, where, anticipating a safe retreat, he was overtaken by the police, and brought up on a charge of burglary.

After an interval of unceasing annoyance for varying periods, and having been the imaginary target for every conceivable form of active hostility, the patient begins to look upon himself as the hero of an unjustifiable and irrepressible persecution—always suffering and never escaping—and he becomes by slow gradations a self-exalted martyr. In this transition stage from persecution to exaltation, during which his insanity appears to be recast, he appeals to mystic explanations to describe the great things that happen to him, he coins new words to express his sensations, he invents weird signs to free himself from the persecution of unseen agencies, and he draws symbols of compasses, skulls, books, stars, angles, diamonds, &c., to exorcise spirits or remove witchcraft and sorcery. Then follows a worn-out neurasthenic stage of exhaustion, when there may be mental torpor, which he explains by accusing unknown persons of stealing his brains or subjecting his thoughts and torturing his body.

This type of insanity, composed of several analogous forms of psychosis, is not very common in asylums, for out of 2500 cases (1450 females, 1050 males) in Claybury, delusions of persecution were only markedly present in less than 20 per cent. of the females and 16 per cent. of the males, and exaltation with systematised delusions in 9 per cent. of the women and 6 per cent. of the men.

ROBERT JONES.

VII. Imperative Ideas.—SYNON.: Fr. *Obsessions mentales*; Ger. *Zwangsvorstellungen*.

DEFINITION.—A pathological state in which the mind is dominated by one idea, compelling the patient to do something or avoid something.

Mental besetments or obsessions are very significant symptoms, occurring, as they always do, in neurotic subjects. They vary greatly in character, and though apparently trivial at first may subsequently assume great importance. Many are of a simple character: one person is obliged to count the gas-lamps or the numbers of the houses; another must tread the pavement carefully, avoiding the joints or stepping on them; another must touch certain things, like Dr. Johnson, who touched the posts as he walked the streets. Some must spell the names over shops and go back to see if they have spelled them right. Others are dominated by various fears: they cannot look down from a window, a cliff, or other high place without a desire to throw themselves down; or cannot sit in a crowded room unless they are close to a door; or are in constant dread of touching or having touched something dirty or infectious, and spend their lives in washing their clothes or hands. This is often carried to extremes, the sufferer fearing not merely dirt but disease, such as syphilis, or defilement of

his food, so that he will eat nothing except what he cooks himself. Such ideas overwhelming a man's whole life, though perhaps absurd at first, render him quite incapable of taking care of himself or his affairs.

Though these besetments vary greatly, they may roughly be divided into those characterised by a desire or *impulse* to do something absurd or foolish; and those arising from a *dread* or doubt—a doubt as to whether the patient has done right, a desire to do it over again, or a dread that something is going to befall him. The most trivial matters assume the greatest importance and render life not worth living. If we look for the very beginnings of such obsessions we find them in the *tricks* which some display—tricks with the hands, tricks with the feet, tricks of gesture, walk, or dress; or in fear of the dark, fear of robbers, ghosts, and the like. All such persons, whether adults or children, are neurotic, many displaying an insane diathesis which fully explains the phenomena. No such obsessions, however slight or absurd, should be neglected. At the outset they may be overcome; later they gain the mastery. All tricks in children should be sternly repressed, and their fears should be judiciously treated, not by ridicule but by example and encouragement. The bringing up of such children is of great importance, and no pains should be spared to repair their degenerated constitution. If the tricks and besetments do not begin until adult life, they equally demand attention. At first a patient may overcome them, and should be urged in every way to resist the impulse and to put aside the fear; and, according to the material to be worked on, we may succeed or not. Sometimes the idea may change, and in place of one fear another may arise, and unfortunately in many cases there is an advance from slight to graver forms, and the patient is possessed by impulses of a violent kind, or fears which render him dangerous to himself or others.

Mickle points out that the best description of some forms of obsession is to be found in the pages of *Lavengro*, by George Borrow, who, he believes, under the guise of different personages in the romance described his own case.

Not long ago a lady from the fear of contamination would take no food but what she ate outside the house or cooked herself; and washed her arms and hands with carbolic acid till they were a mass of sores. Clouston narrates the case of a medical man who placed himself under restraint because he was haunted by an impulse to commit murder or suicide. All such should be carefully observed and recorded, as they throw great light on criminal cases and on the evidence to be given in courts of law. See IMPULSIVE INSANITY.

G. F. BLANDFORD.

VIII. Impulsive Insanity.—Violent acts are committed under an insane impulse by many patients whose insanity is plain and acknowledged. They may be done under the influence of delusions or hallucinations; but the term *impulsive insanity* is commonly applied to a disorder manifested, not by delusions and similar symptoms, but by acts of violence to which a patient is driven by blind, uncontrollable, and morbid impulse, whereby the will and the reason are overpowered for a longer or shorter time. These are for the most part acts of *suicide* or *homicide*; and in connection with the

latter, great controversy has arisen as to the responsibility of persons committing them. Here, as in moral insanity, there are no delusions; frequently no change will have been detected in the individual prior to the act, nor will there be observers of it. And it is a fact that the impulse may be satisfied and exploded in the act, and having thus found a vent may be felt no longer, at any rate for a time.

Impulsive acts of violence are committed continually in asylums, and many patients on recovery have related the history of the impulsive feeling and their difficulty or, it may be, their failure to control it. A medical man placed himself in Morningside Asylum, being haunted by a constant impulse to commit homicide or suicide which he feared he could no longer resist. He had been overworked, but with rest and treatment recovered, returned to his hard practice, and relapsed. A youth nearly murdered his mother from homicidal impulse which he vainly tried to resist. He had been peculiar from twelve years of age, and noticed as such by his fellow clerks. Such insane impulses may exist without apparent symptoms, and without discoverable delusion or hallucination. They are akin to the imperative ideas or obsessions which beset some people (*see IMPERATIVE IDEAS*). Such tricks in the neurotic may develop till the *obsession* becomes a *possession* and rules the whole life. Thus may these persons advance to insanity, their higher centres losing control more and more, and these absurd and harmless but imperative ideas becoming delusions or leading to insane acts.

Many acts of violence are committed through delusion or hallucination, though this may not be recognisable without much searching, or not till after a long time. Orange mentions a woman who murdered her child and was acquitted as insane, the act being looked upon as one of sudden uncontrollable impulse. But at Broadmoor she confessed that she did not want to live and remembered that she thought it would be the right thing to kill the children before she killed herself. The act was committed under a delusion. A large number of insane and apparently impulsive acts arise from hallucinations of hearing, 'voices' as they are called. Many a murder has been committed, the victims being perfect strangers, because the lunatic has heard a 'voice' calling him filthy names or commanding him to kill. These 'voices' become a terrible persecution and cause intense anger against the unknown persecutors. And if on some occasion the patient fancies that he hears them from a chance bystander, he may murder him not from an uncontrollable impulse, but from the delusion. Yet the hearing of such voices is often carefully concealed and may require close search.

The medical witness will in the case of homicide carefully examine and pay special attention to the following points:—

(a) The nature and character of the act must be noted. The presence or absence of motive may often assist us. When the victim is near of kin and dearly loved, suspicion of insanity will at once arise. When, on the other hand, it is a perfect stranger, never before seen, where there has been no previous meeting or quarrel, the same suspicion will arise. The method of the act may guide us somewhat, but not much. There may be premeditation, though generally there is not.

(b) The demeanour of the prisoner after the act may assist us. Were there, or were there not,

attempts to conceal it, or to escape detection and arrest, and, if so, what was the nature of them? What was said in explanation? It sometimes happens that there is complete unconsciousness or forgetfulness of what has occurred, and we may then strongly suspect the presence of epilepsy.

(c) We must closely inquire into the family history, and shall often find that, in cases of impulsive homicide, the family of the accused has suffered with insanity. And where this is so, we may also find that from youth the accused has been deficient and weak in intellect, or odd and eccentric. The weak-minded, in fact, may be grouped in a special class of homicides. As there is a weak-minded moral insanity, so there is a weak-minded impulsive homicidal insanity, the sufferers from which have not infrequently been hanged, their insanity not having been sufficiently marked to absolve them from legal responsibility. Fits in childhood may contribute to this state. And throughout, at the age of puberty, or in adult life, there may be slight but sure indications of the insanity that has been inherited, which are displayed in an impulse to mischief, homicide or suicide, even as in others the tendency is shown in ordinary attacks of insanity.

(d) We must look very closely for symptoms of a history of epilepsy. Such indications as nocturnal micturition or a bitten tongue may guide us to the truth; while in acknowledged epileptics it may happen that the homicidal attack takes the place of the ordinary convulsion, and without the occurrence of the latter there may be a period of unconsciousness and unconscious action lasting, perhaps, for days. *See EPILEPTIC INSANITY*.

The occurrence of one homicidal attack of a strange or anomalous character may make us fear its recurrence; and when we have to examine a criminal who has committed one act of this kind, it is important to inquire whether he has ever at any former time done any sudden act of violence of a similar description. For this reason such patients should not be released from an asylum, except under special precautions.

G. F. BLANDFORD.

IX. Mental Stupor and Catatonia (*κατά, down; τένος, tension*).—Stupor is a state in which the outward signs of mentation are in abeyance.

ÆTIOLOGY.—This is the same as in other forms of insanity. Among the stresses most likely to produce this condition are mental or moral shock, and sexual excess in an unstable individual.

CLASSIFICATION.—There are three forms of stupor recognisable: (1) Anergic Stupor; (2) Delusional Stupor, or Melancholia Attonita; and (3) Secondary Stupor. The terms 'primary dementia' and 'acute dementia' are sometimes used for certain cases of anergic stupor. These terms are misleading because they erroneously bring these curable conditions into the category of true dementia which is permanent weak-mindedness and an incurable condition.

SYMPTOMS.—For brevity and convenience we shall take the symptoms of *anergic* stupor and *delusional* stupor together, merely pointing out the distinction between them, for not uncommonly the two forms are observed to interchange in the same patient. The mental symptoms are to a large extent negative in character. The patient stands or sits unoccupied with a vacant expression, and he

takes no apparent heed of his surroundings. There is marked mutism, and saliva not uncommonly dribbles from the mouth. The pupils are dilated. Food is refused, and when placed in the patient's mouth may remain there for a long time unmasticated. The extremities are cold and blue and frequently œdematous. The pulse is feeble, and respiration is slow and shallow. The evacuations are passed involuntarily, and the patient usually suffers from constipation. Nutrition fails rapidly as in many other forms of acute mental disorder. The hair and nails become brittle, pustules and small superficial abscesses may occur, indicating nutritional change in the skin. There is amenorrhœa in the female. At night the patient may remain quietly in bed, but sleep is usually very deficient. The memory is said to vary in the two conditions. In the anergic form the memory is almost absent, so that on recovery the patient remembers little or nothing of his illness; on the other hand with the delusional type memory may be fairly accurate. Delusions may or may not be present in the anergic form, but they form an important symptom in melancholic stupor. Probably the condition of the patient is one in which his mind is preoccupied and dominated by some delusion which causes him to look upon those about him as his enemies and persecutors. In anergic stupor the patient, though dependent on others to look after him, is unresistive and apathetic; he can be dressed, fed, and attended to without difficulty: on the other hand a case of melancholic stupor will usually resist everything that is done for him.

In *secondary stupor* or post-maniacal stupor the symptoms closely resemble those already described, but differ in that the stuporose condition is more transitory and usually less severe. In these cases the patient can usually be aroused, and often be persuaded to speak; in fact in its milder form the condition is purely one of lethargy and apathy.

Stoddart supports the above classification of stupor, which is based on mental symptoms, by his observation of certain physical signs in these conditions. Delusional stupor (*Melancholia attonita*) in common with other forms of melancholia is characterised by a form of rigidity which mostly affects the muscles of the trunk and larger joints. Cases of post-maniacal stupor or secondary stupor show a form of anæsthesia which affects the limbs, especially at their peripheral parts. In anergic stupor the above-mentioned rigidity is wanting, but in its stead we find either the cataleptic condition known as *flexibilitas cerea* or complete flaccidity. Similarly the anæsthesia described above is wanting in anergic stupor; these patients do not react to painful stimuli, but this is not due to true analgesia, since the patients on their recovery recall vividly the details of the investigation.

Catatonia.—This disorder was first described by Kahlbaum in 1874. It is a form of insanity by no means common in Great Britain. It is divided into stages. During the first few weeks the condition is one of ordinary depression, followed sooner or later by excitement. This excitement is shown either by a period of acute mania or by a state of agitated melancholia. The second stage is ultimately followed by a condition which is marked by immobility with rigidity (*attonita*); this is the characteristic stage of the disorder. There is now absence of all spontaneous movement, and with this more or less complete immobility. Passive

movements are met by a powerful resistance (*negativism*). This rigid immobility not infrequently is from time to time interrupted by movements incessantly repeated in an automatic manner (*stereotyped movements*). Throughout this stage mutism is a characteristic symptom, but this mutism may be broken by periods during which the patient repeats words or phrases in a monotonous and automatic manner (*verbigeration*). The other symptoms of catatonia resemble those found in ordinary stupor. Vaso-motor disturbances are common, respiration is usually shallow and slow. There is not infrequently refusal of food. If the patient does not recover he generally passes on into a condition of ordinary secondary dementia, but in addition the symptoms of stereotyped movement and verbigeration as a rule persist.

PROGNOSIS.—The prognosis of anergic stupor is fairly good, although in a limited number of cases the recovery is delayed for as long as three years. In the delusional type of the disorder and catatonia, the chances of recovery are not so hopeful. The peculiar liability to phthisis must never be lost sight of in dealing with all forms of stupor. Cases of secondary stupor usually get well: in fact this condition is commonly a stage on the road to recovery.

TREATMENT.—The treatment of all forms of stupor must, during the early stages, be stimulating and supporting. Food must be generous and plentiful; and if nourishment is refused artificial feeding must be resorted to without delay. Constipation must be relieved, and the bowels regulated. In some cases massage and passive exercises have proved beneficial: in others cold or tepid shower-baths may be used with advantage, but these must not be persisted in if there is no good reaction following the bath. Turkish baths of short duration may be also tried. General tonics should be prescribed, and, if necessary, stimulants. Maltine and cod-liver oil should be given once or twice a day if there is loss of weight. MAURICE CRAIG.

X. Moral Insanity.—SYNON.: Fr. *Manie sans Délire; Folie Raisonnée; Monomanie Affective*; Ger. *Gemüthswahnsinn*.

Under the names of *moral insanity*, *emotional insanity*, *impulsive insanity*, *affective insanity*, has been described the disorder of certain patients, which is manifested by insane actions and conduct rather than by insane ideas, delusions, or hallucinations. Such persons are sometimes said to be of whole and perfect intellect, though unsound in the moral and emotional part of their brain. They come under the notice of medical men not so much for purposes of treatment as for diagnosis. Their conduct being chiefly displayed in foolish or violent acts, they require to be restrained, and the question arises, Is this conduct badness or madness? Are they responsible for it or not?

Objections have been made to the term *moral insanity*, and it has been proposed to call it *insanity without delusion*, inasmuch as it does not constitute a defined and well-marked disease, like acute delirium or general paralysis. Every patient may at one time or other be 'morally insane'—that is, may not have reached the stage of delusions, or may have recovered from it, and every patient may commit 'impulsive' acts of violence, whether his insanity is displayed in other ways or not.

By *moral insanity* is to be understood a disorder of mind shown by an entire change of character

and habits; by extraordinary acts and conduct—extravagance or parsimony; false assertions and false views concerning those nearest and dearest—but without absolute delusion. Such a change may be noticed following any of the ordinary causes of insanity. It may follow epileptic or apoplectic seizures, or may be seen after a period of drinking. Its approach is gradual, as a rule, rather than sudden; and the extraordinary character of the acts may not at first be so marked as subsequently. Friends wonder that a man should say this or that, or should do things so foreign to his nature and habits, but some time may elapse before they can convince themselves that such conduct is the result of disease; and the acts may be such that many will look upon them even to the last as signs merely of depravity. Such insanity, of course, varies in degree. When it is well marked, and the conduct is outrageous, there will be no difficulty in the diagnosis. But it may be less marked, and may consist of false and malevolent assertions concerning people, even the nearest; or of little plots and traps to annoy others, in which great ingenuity and cunning may be displayed. And there will be the greatest plausibility in the story by which all such acts and all other acts will be explained away and excused. It would seem sometimes as if a universal badness had taken possession of the individual, yet a badness so inexplicable that it can only be looked upon as madness. Where we can ascertain that this condition of things is something which has come over the patient, being formerly absent, and that he is altogether changed, we may suspect insanity. But much examination and opportunity for examination may be needful before we can sign a certificate, for such people are often very acute, and quite on the alert. They have no scruples about falsehood, and will deny or justify everything with which they are taxed; and where the insanity is manifested in conduct, the medical man may never be a witness of it, and is obliged to receive on hearsay that which the patient strenuously denies. Careful inquiry, however, will probably reveal the origin and cause of the change. There may have been a period, though short, of acute insanity—as acute mania or melancholia—which passed away and left this as a permanent condition; or it may be the precursor of a more advanced stage of the disorder, one marked by the ordinary symptoms, as delusions and hallucinations. If the change has been rapid and progressive, if the sufferer has become more and more outrageous and eccentric, it is likely that in a short time unmistakable insanity will be displayed; but some cases progress slowly, and steps for restraint have to be taken before anything like delusion is to be found. It may be necessary to prevent a man from squandering all his property—a common symptom in this variety—or from wandering from home and absenting himself no one knows where, or keeping low company. And when a man previously quite sober suddenly takes to drinking, the question may arise whether this is not the effect of insanity. Great difficulty may be found in proving the latter, but unquestionably it is often the case. Here, however, if the habit is indulged in, the patient will most likely get rapidly worse, and then restraint will be more easily enforced. An alteration in habits and conduct is not infrequently found in the aged, and may be manifested by drinking or debauchery or general emotional change. Here a

comparison with the former life of the individual may assist the diagnosis. See SENILE INSANITY.

Moral insanity may be the precursor of general paralysis; it may also be the sequel and result of a more severe insanity; it may be the outcome of apoplexy, or of a blow or other damage to the brain. It may be one of the alternating states of the so-called *folie circulaire*. Here a period of depression alternates with one of excitement, gaiety, self-glorification, or irascibility, and the latter may be one closely resembling that usually called moral insanity, and evidenced by exaggerated conduct and absurd acts. It may follow a simple attack of epilepsy, or may be the precursor of such attacks, being a part of that epileptic condition known as masked epilepsy. See EPILEPTIC INSANITY.

The one constant and marked feature of this insanity is the absence of delusion; but we are not on this account to argue that the intellect is sound. There is often great acuteness and cunning displayed by such patients, yet along with the cunning there may be the most silly and foolish conduct. Often there is great acuteness shown by those who have delusions, but because of the latter we say their intellect is disordered. Yet it is proof of disorder of the intellect if a patient spends his capital as though it were income, defends and justifies the most outrageous acts, and cannot be made to see that they are outrageous. Close examination will probably reveal the fact that there is very considerable intellectual lesion in these cases. There is a want of the power of attention and concentration of ideas on a subject. A patient commences a story of his grievances, and in two minutes is far away from his theme, and is boasting of his virtues or conduct, and no amount of bringing back will enable him to give a definite and succinct account of what he has to complain of. Such rambling is a marked symptom of this insanity, and a strong indication of a weakened intellect.

There is one more form of moral insanity which is, perhaps, the hardest of all to diagnose and estimate. It is the congenital moral defect occasionally met with in persons who have been from birth odd and peculiar, and incapable of acting and behaving like other people. They can hardly be called idiots or imbeciles, for they may exhibit a considerable amount of intellect and even genius in certain special directions. We shall generally find that they are the offspring of parents strongly tainted with insanity, epilepsy, or alcoholism, and many in childhood are the subjects of fits, chorea, or other neuroses. They are incapable of being instructed like other boys and girls; are often frightfully cruel towards animals, or their brothers and sisters; and seem utterly incapable of telling the truth or understanding why they should do so. The offspring of intemperance and poverty, and often lacking the special training which is essential, they become the chronic inmates of prisons, and it is most difficult both for medical and other prison officials to say how far they are responsible, and how far not. See IDIOTCY.

G. F. BLANDFORD.

XI. Insanity in special Diseases.

Brain, Tumours of the.—Brain-tumours in some cases affect the mind to a considerable extent. The symptoms depend on the parts of the brain involved. Generally with advancing pressure due to growths within the skull, sluggishness, indolence,

loss of will-power, and general disregard of the surroundings and of conventional duties are noticed, along with somnolence, disregard of cleanliness, and irritability. It has been noted by Wilks that patients with brain-tumours and coarse brain-disease often have their hands placed over the genitalia. Optic neuritis and implication of cranial nerves assist diagnosis. See BRAIN, TUMOURS OF.

Cholera.—Few cases are admitted into asylums during epidemics of cholera, but there are many cases of acute mental disorder associated with the disease. Acute mania may arise or simple melancholia, often of the stuporose or hypochondriacal type. Delusional insanity with ideas of persecution has also been described, and permanent mental weakness has been seen by the writer following an attack of cholera. In most cases where the disease itself has passed the patient recovers from the mental sequelæ.

Chorea.—Chorea has been shown by Gowers to occur more in neurotic families than in others. In nearly all cases there is more or less marked mental weakness, which depends on the duration of the disease, the severity of the movements, and the physical health of the subject. Age too has a distinct influence: the younger the child the greater the danger of permanent mental defect. The best treatment is time and healthy surroundings, with organised gymnastics; sea-air and simple diet are also useful. In some of the older cases of chorea a delirious state may arise, and this may pass into true delirious mania of the most dangerous type. Death generally occurs in such cases; the only hope lies in the administration of abundant fluid food with stimulants. As an after-effect of the delirium there is great tendency to some mental weakness which is allied to the weakness of neurasthenia, and needs rather rest than stimulation.

Diabetes.—Diabetes is common in neurotic families; thus insane or highly neurotic parents often have diabetic offspring, and diabetic parentage may lead to neurosis in the next generation. With diabetes there may be acute mania, but it is more common to meet with mental weakness and melancholia of a hypochondriacal type. In some diabetics, when mental disorder appears, the sugar disappears from the urine, at least for a time. Diabetes not infrequently occurs in general paralytics. In these the sugar may disappear for a time, but returns when the patient passes into dementia. In insanity associated with diabetes treatment must be directed to the latter disease.

Disseminated sclerosis may give rise to symptoms of mental disorder resembling in many ways the symptoms of general paralysis of the insane, especially that form which has been called 'adolescent' or 'developmental general paralysis.' The chief characteristics which distinguish disseminated sclerosis are the absence of syphilitic history, the peculiar staccato speech, the rhythmic tremor of the upper extremities, and the irregular paralysis of certain groups of muscles.

Exophthalmic Goitre.—The true relationship of this disease to insanity is not fully understood, but we recognise first the occurrence of Graves's disease in neurotic families; next, that it may definitely affect the nature of the symptoms; and finally, that there are a few cases in which the mental and bodily disorders are directly connected. It is noteworthy that only one or two of the characteristic symptoms of exophthalmic goitre may be

present along with mental disorder, as in some cases of general paralysis; and also that the mental and bodily symptoms may be present together in recurring mental illnesses. Owing to the peculiar aspect produced, young people may think that they are noticed and spoken about by others. This may lead to melancholia or to delusional insanity. In some cases acute enlargement of the thyroid gland, with accelerated pulse and prominent eyeballs, is associated with restless, sleepless activity, which passes into acute mania of either the hysterical or the delirious type. Such cases not infrequently die of some intercurrent trouble, such as diarrhœa. The treatment must depend on the symptoms of the general disease: feeding, rest, and sedatives, such as belladonna and hyosine, seem to act best.

Gout.—In many cases associated with the onset of acute attacks of gout there is some marked intellectual change. In some there is depression, while in others there is unusual intelligence and brilliancy. Suicidal tendencies develop in some persons before the attack. In many cases of so-called 'suppressed gout' there is a considerable amount of mental depression, generally of a hypochondriacal type. Some patients believe they are dying, or that they have cancer or some certain cause of death. Others have vague but most serious mental depression; and in some of the most determined suicidal cases suppressed gout is the exciting cause. Patients may be relieved from mental depression immediately on the appearance of articular gout. In such cases purgatives and free use of Turkish baths are the best methods of treatment. Occasionally during gout acute mania, often of the delirious type, may arise. This is what used to be called 'Metastasis of gout to the brain.' In these cases the prognosis is very grave, and the treatment must be the free administration of stimulants and chloral hydrate.

Heart-disease.—Intellectual capacity is related both to the brain and to the circulation; and, as might be expected, irregularities of blood-supply may be associated with irregularity of cerebral function. There is, however, no definite connection traceable between forms of heart-disease and mental disorders. It appears to be true that with mitral insufficiency there is commonly a tendency to mental depression (Dickson). The writer has frequently met with a true melancholia with suicidal tendencies in patients with valvular incompetence. Restlessness, with mental exaltation, may be found in cases with aortic trouble, and great hypertrophy of the left ventricle. Temporary rapidity of the heart's action is met with in some patients with mania, and the pulse is generally slow in stuporose states.

Influenza and other Febrile diseases.—Soon after the first of the recent epidemics the writer described influenza as a frequent exciting cause of mental disorder, and this has been confirmed by general experience. Influenza may set up various forms of insanity which may occur at various periods of life; there is no specific form deserving the name of influenzal insanity. Influenza may be the predisposing or the exciting cause of an attack. It acts most prejudicially in those of neurotic stock, those who are already degenerating, and those who have suffered from previous nervous illnesses; hence it specially affects the intemperate. Probably the influenzal poison acts directly on the brain; thus it may relieve existing insanity or modify the attack.

It produces mental depression, and the various forms of melancholia more frequently than mania; it may, however, start acute delirious mania, and there is serious danger of this developing when the attack of influenza is associated with childbirth. Greater danger to the nervous system apparently arises from frequently repeated attacks than from the existence of a high degree of fever. This form of disease frequently leads to suicide; it may start delusional insanity, with ideas of persecution in the organically neurotic and in the drunken, and may thus lead to crimes depending on the delusions. Its treatment should be chiefly expectant, and the patient should be placed in healthy and invigorating surroundings. Sea-air is very useful, as is also cold fresh air in mountains during the summer. Free administration of alcoholic stimulants is beneficial, and for the sleeplessness which is one of the prominent symptoms alcohol, chloral hydrate, and paraldehyde are among the most useful remedies.

What has been said of influenza holds good almost exactly of the disorders of mind following other fevers. They affect chiefly those who are of neurotic or of degenerating stock, or who by alcoholic or other excesses have induced in themselves a condition of instability. Any fever accompanied by delirium may start delirious mania, or in predisposed subjects may set up any other form of insanity to which the patient is liable. The height of the fever has some influence, but this too depends on the neurotic tendency of the patient. Prolonged high temperature leads in these cases to more or less complete and enduring dementia. Such attacks may occur with measles, and several have been described as following mumps. Pneumonia may start neuroses, and, in the writer's experience, scarlet fever is particularly dangerous in this relationship. Small-pox is also dangerous during the acute stage, and later the disfigurement may lead to a morbid self-consciousness which tends to develop ideas of suspicion, ending in delusional insanity. Typhus, with its acute onset and high fever occurring in young persons, has a very powerful effect in upsetting the mental balance. In very many cases the disorder is slight and temporary, so that the only evidence of it is loss of recent memory, general irritability, slight tendency to hallucinations and emotional weakness. Fevers occurring in the acutely insane modify the symptoms for a time, but do not as a rule check them. In cases of subacute mental disorder, or where the acute stage has passed, fevers may lead to complete cure; in chronic cases the fever may produce temporary relief; but as a rule, when the fever has subsided the mental symptoms recur. In patients subject to recurring mania the fever may start an outbreak.

Malaria.—There are several conditions under which insanity occurs with malarial symptoms. With the febrile stage there may be restlessness, sleeplessness, depression, and later acute mania of the most dangerous delirious type. The acute symptoms may recur at regular intervals associated with the febrile stage of the disorder; in these cases the headache, the full arteries, and the congested face mark a difference from simple mania. The mania may suddenly break out in malarial patients, but in such cases alcohol, syphilis, or exhaustion may have been an associated condition. After the passing off of the acute symptoms of malaria there may appear mental disorder of various forms. These cases as a rule belong to the unstable or neurotic class, and

among them stupor is more frequent than mania. In some patients malaria leaves behind it some mental disorder or nervous disease; thus sleeplessness or neuralgia may occur, or definite delusions of a limited nature, which may or may not be associated with hallucinations. Though quinine may be tried in all these cases it is common to find that it fails to do good; and prolonged courses of arsenic with baths and general hygienic treatment will have to be tried.

Myxedema.—It is noteworthy that with defect or disease of the thyroid gland mental deficiency is noticed in certain cretinoid idiots, who assume an aspect like that of the myxedematous adult. In the latter, with the increase of the symptoms of myxedema, there may be dulled perception, slow reaction, and consequent mental confusion. Patients thus misunderstand what is said and what is taking place near them, and may believe that things are done to annoy them. Hence ideas of plots, conspiracies, and the like arise. In some cases this may be followed by or associated with exaltation of ideas, the patient believing himself to be royal or great. There is slow progressive loss of will-power and of control, but most of all progressive loss of memory and of power of taking interest in surroundings; this leads on to dementia, in which state the patient may live long. The writer has met with a fairly large number of elderly women who, with progressive loss of mental power and with the presence of some delusions, have many of the symptoms of myxedema, though in a modified degree—a myxedematous degeneration rather than myxedema. In all cases with any of the symptoms of this disease it is well to try the effect of thyroid-treatment; but this must be done with care, for some of these patients, though apparently tolerant of large doses, yet after its continued use fail in general health and appetite. After administering the drug for a fortnight it is well to discontinue it for a few days, or even for a week or more, before giving it again, thus allowing short intervals between the periods of treatment.

Pellagra.—This disease is rarely met with in England, and is supposed to occur from eating diseased maize. It rarely runs its course without the appearance of some mental symptoms, and is often the starting-point of one or other form of mental disorder. It causes marked melancholic symptoms, with general sluggishness of thought, feeling, and reaction. It leads in some cases to delusional insanity, with hallucinations of the senses, but more often passes into temporary stupor or partial dementia. Suicide is common in these cases, and it has been said there is special tendency towards death by drowning. In some cases the disease has much the aspect of general paralysis of the insane, but there is little or no affection of speech, and the patients rarely show any exaltation of ideas. Change of diet and of surroundings leads to recovery in most of the cases, but in some permanent mental weakness arises.

Phthisis.—Clouston was one of the earliest to point out the special connection of phthisis with insanity. It had long been recognised that an undue number of deaths from phthisis occurred in asylums. This is probably due chiefly to direct contagion, but it appears that the neurotic afford a specially suitable nidus for the development of this disease. In phthisical insanity the whole aspect of the pulmonary disease changes. The patients com-

plain little of cough, expectoration, and the usual troubles; instead of being buoyant they are generally disagreeable and complaining, readily believing that persons about them annoy, worry, or interfere with them. They often refuse their food, and say poison is in it. It is still doubtful at what stage of phthisis the mental disorder generally occurs. Some think that it is most common in the earlier stage—that of consolidation of the lung, and it certainly is true that often with the development of active bodily signs of phthisis the mental disorder passes off. There is a form of alternation, the mind being better when the lung-disease is making progress, and worse when the pulmonary symptoms are dormant. The new modes of treatment seem to be the best for patients who are both insane and phthisical—change, healthy surroundings, fresh air, and simple living. The hotter climates do not suit these patients so well as colder regions.

Sunstroke.—Great difference of opinion has arisen as to the part played by insolation in producing insanity, but it appears that though a great deal of mental disorder really depending on alcohol, syphilis, or other causes of degeneration has been attributed to sunstroke, yet a certain number of cases of insanity actually depend on this cause. Langdon Down believed that a number of children of Europeans who were born or passed some time in the tropics became idiots or imbeciles as the direct result of heat or sunstroke; such patients frequently had fits and became restless, troublesome, and without moral sense. Hyslop thinks that a certain number of the insane become so as a direct result of the sun. The difficulty is to decide between general paralysis, alcoholic insanity, certain forms of dementia and syphilitic brain-disease, and effects of the sun. In true insanity depending on insolation the symptoms are generally those of progressive dementia, resembling general paralysis; but instead of developing, these symptoms remain stationary for years or even pass off more or less completely. It is possible that many cases of cured general paralysis have really been of the type described. In some of the cases due to insolation the mind remains feeble, but efficient, for many years. No special treatment can be followed: rest, freedom from alcohol, and avoidance of the sun's rays and of heat are the chief indications.

G. H. SAVAGE.

INSENSIBILITY (*in*, not; and *sentio*, I perceive).—This word signifies either loss of consciousness, or merely loss of sensation in a particular part of the body. See CONSCIOUSNESS, Disorders of; and SENSATION, Disorders of.

INSOMNIA (*in*, not; and *sonnus*, sleep).—Want of sleep, or sleeplessness. See SLEEP, Disorders of.

INSPECTION (*inspicio*, I look upon).—See PHYSICAL EXAMINATION; and NECROPSY.

INSTALLATION (*in*, into; and *stilla*, a drop).—The method of applying remedies to a part in the form of drops. Installation is chiefly employed in connection with the eye.

INSUFFLATION (*in*, into; and *sufflo*, I blow).—This term is applied to a method of applying remedies in the form of powder to the throat

and respiratory passages, by blowing them through a tube into these parts. See INHALATIONS, Therapeutic Uses of.

INTEGUMENTS, Diseases of.—See SKIN, Diseases of.

INTEMPERANCE, Effects of.—See ALCOHOLISM.

INTERCOSTAL NEURALGIA.—Any of the dorsal nerves may be the seat of neuralgia, not differing materially in its symptoms from neuralgia affecting other mixed nerves, but especially important from a diagnostic point of view. The pains are paroxysmal; usually affect the region of distribution of the anterior division of one or two of the dorsal nerves; and are confined to one side, most frequently the left.

ÆTIOLOGY.—The female sex, neurotic heritage, and weak general health predispose to intercostal neuralgia. As determining causes may be mentioned blows; the action of cold; local injury to the nerves from the growth of thoracic aneurysm or tumour; and disease of the vertebrae. Exhaustion from over-suckling, menorrhagia, or leucorrhœa; irritation from cracked nipples; and pregnancy, are all occasional but important causes of this form of neuralgia. The pain met with in the chest in early cases of phthisis is not infrequently due to intercostal neuralgia. It is probable that, in a large proportion of cases, the neuralgic pain is due to neuritis of one or more intercostal nerves.

SYMPTOMS.—Pain is complained of at some part of one side of the thorax or abdomen, most often in the region innervated by the sixth, seventh, eighth, and ninth intercostal nerves, and much more frequently in the front or side than behind. It is occasionally found in the axilla and inner side of the arm. The pain may be intermittent, occurring in paroxysms, varying in number from a recurrence every few minutes to only two or three such during the twenty-four hours; or there may be persistent pain of a dull character, interrupted at varying intervals by darts of a very sharp kind, which may sometimes be referred with precision to the course of the neighbouring nerve. The pain is described as 'tearing,' or resembling such injuries as a 'stab of a knife,' or 'horing with a red-hot iron.' The acts of coughing and sneezing, as well as any rapid movements of the body, are apt to increase the distress, but the pain is also independent of these disturbances, and will attack without any such provocation. The pain is sometimes more of a wearing than acute character, and the rest will often be destroyed by it. Painful points are sometimes to be discovered in the following situations: 1. Over a spinous process corresponding to the emergence of the affected dorsal nerve from the intervertebral foramen. 2. At the side of the chest or abdomen, where the lateral branch becomes subcutaneous. 3. Near the sternum or at the margin of the rectus abdominalis muscle, at any part down to the pubes, where the termination of the nerve supplies the skin. The skin in the neighbourhood of the tender points is sometimes so hyperæsthetic that the pressure of the clothes is painful. In epileptics and other highly neurotic patients, intercostal neuralgia is often associated with palpitation of the heart, and the pain is usually referred in a vague manner to that organ. Close examination will show that it is in the chest-wall, and tender points may generally

be discovered. The affection is not accompanied by fever. The paroxysms of pain may produce fainting and vomiting. They often cause dyspnoea, with an anxious expression of face, from the inability to draw a full breath without starting the pain.

COMPLICATIONS.—Intercostal neuralgia is sometimes accompanied by herpes zoster. The pain usually precedes the appearance of the eruption, but it is occasionally coincident only, and sometimes comes after it; more often than not it outlasts the eruption, possibly for a long period. In certain cases actual pain lasts but a few days, but is succeeded by an intolerable itching, which is described as being under, not in, the skin. This sensation is said to be felt less in walking than when at rest.

Not infrequently neuralgia of some other nerves, either at a distance, as the fifth, or anatomically near, as the brachial plexus, occurs as a complication of intercostal neuralgia. This is especially likely in cases happening in the period of bodily decay. It is then, too, that the affection may occasionally be accompanied by attacks of angina pectoris.

DIAGNOSIS.—Absence of pyrexia, as shown by the use of the thermometer; the intermittence of pain, and its occurrence irrespective of respiratory movements, although liable to be precipitated by them; and the results of physical examination, serve to distinguish intercostal neuralgia from pleurisy, a condition with which it is very apt to be confounded, on account of resemblance in the stabbing character of the pain. It should be remembered, however, that exceptionally no rise in temperature may accompany the painful stage of pleurisy.

From muscular rheumatism it may be discriminated by the presence of the small and characteristic tender points; by tenderness of the spinous processes on pressure; and by the pain being found not to be dependent upon movements. The same features serve to distinguish it from myalgia, especially that form which often comes from long-continued use in an unaccustomed manner of some muscle attached to the ribs, as when a person unused to carpentering handles the saw energetically for a long time.

Physical examination and the presence of pyrexia will preserve from the error of confounding the dull pain often noted in pneumonia with that of intercostal neuralgia.

Pains of a stabbing, plunging, or electric-shock-like character are often experienced in the intercostal spaces in the course of tabes, and it is important not to confound this disease with a simple attack of intercostal neuralgia. The distinguishing points are the occurrence of similar pains coincidently or alternately in other parts of the body, especially in the lower extremities; the absence of patellar tendon-reflex; and the characteristic gait (if present)—all of which mark tabes. *See* TABES DORSALIS.

PROGNOSIS.—As in the case of other forms of neuralgia, that of the intercostal nerves can hardly be said to be attended by danger, though it must be allowed that in some very rare instances the severity of the pain appears to have actually destroyed life. It is apt, however, to be of troublesome duration, dependent on the cause, lasting for periods of weeks or months, and liable to recurrence.

TREATMENT.—Such should be made in other branches of the same nerve, and in the distribution of neighbouring nerves, for any source of irritation

which it is possible to remove. Constipation should be treated by three grains of Blue Pill, followed by some Friedrichshall or Hunyadi János water, repeated on two or three occasions. Quinine should be given in doses of from five to ten grains twice a day; and if there should be a state of anæmia, iron should be added. Phenazone in doses of from ten to twenty grains may be given two or three times a day, if necessary. Exposure to cold and damp must be avoided; while the surroundings generally should be favourable to improving the nutrition and tone. If the pain be very acute, and sleep prevented, morphine may be injected hypodermically in the neighbourhood of the affected nerve, commencing with a dose of a twelfth of a grain, and increasing this, if necessary, to a quarter of a grain in the twenty-four hours. This dose should not be repeated, however; and it is better to be satisfied with a repetition of the smaller dose, if required. Small blisters (size of half a crown) may be applied to the neighbourhood of the spinal column, near the point of emergence of the affected nerve, one succeeding another as it heals. The continuous voltaic current, from about ten to twenty cells, Leclanché or Stöhrer, may be applied, one sponge on the spine and the other upon the painful points in turn. *See* NEURALGIA; and HERPES ZOSTER.

T. BUZZARD.

INTERLOBULAR (*inter*, between; and *lobulus*, a little lobe).—Situated in the tissue between the lobules of any organ. A good illustration is *interlobular emphysema*, in which air occupies the tissues between the lobules of the lungs.

INTERNAL CAPSULE.—The internal capsule and adjacent ganglia—optic thalamus and corpus striatum—are especially liable to lesion from thrombosis and rupture of their blood-vessels. These are furnished principally by the middle cerebral artery, which in the first part of its course sends off numerous straight twigs, which sink into the anterior perforated space, and supply the corpus striatum and the adjacent part of the optic thalamus. Owing to their position, and direction as regards the main current, they are easily ruptured or blocked up, and owing to their being of the nature of 'end arteries,' and almost destitute of anastomoses with other cerebral arteries, thrombosis rapidly leads to softening of the regions which they nourish.

SYMPTOMS.—The symptoms of lesion of the internal capsule may be divided into three groups or stages.

First stage.—To this stage belong the symptoms usually accompanying an apoplectic seizure (apoplexy), as also the loss or diminution of sensation on the opposite side of the body, which sometimes occurs in consequence of pressure on, or functional interference with, the sensory tracts of the internal capsule. There is also to be observed complete paralysis of voluntary movement on the opposite side of the body, occasionally varied by convulsive spasms of the paralysed side, and conjugate deviation of the head and eyes towards the sound side. This last symptom is due to the centres for the head and eyes of the opposite hemisphere suddenly losing their antagonists. The temperature of the paralysed side is, as a rule, higher than that of the sound side. The total paralysis and flaccidity of the opposite side of the body, and conjugate deviation of the head and eyes, are transient symptoms, lasting from a few hours to a day or two.

Second stage.—This stage includes those symptoms which continue for a variable period, after those depending on the suddenness and disturbing effect of the lesion have passed off. They constitute the common type of hemiplegia or paralysis of voluntary motion on the side opposite the lesion. The face, arm, and leg, and to a certain extent the thoracic and abdominal muscles on one side of the body, are affected. The paralysis does not affect all these parts equally. As a general rule it may be stated that those movements are most affected which are most independent of those of the opposite side, and which are most complex and delicate. Hence the movements of the hand and arm are more affected than those of the face or leg, owing to the fact that these are more commonly exercised in associated or alternating action with those of the other side. The facial paralysis is most marked in the lower facial region. The orbicularis palpebrarum is more or less paretic, but never paralysed to the extent which occurs in Bell's or peripheral facial paralysis, depending on lesion of the seventh nerve. The angle of the mouth on the paralysed side hangs lower, and the tongue deviates slightly to the paralysed side. The weakness of the facial muscles is best brought out when the patient smiles or tries to whistle. The face then becomes drawn to the sound side. While some volitional control may have been acquired over the leg, the hand and arm remain perfectly motionless.

In the process of resolution the leg recovers before the arm, and as a rule the recovery proceeds from the proximal to the distal end of the limb, the movements of the shoulder and hip being regained before those of the hand or foot. The flexors regain their power before the extensors.

The reflexes upon the paralysed side are altered: thus the knee-jerk and other tendon-reflexes are increased, an ankle-clonus is obtained, and the plantar reflex is of the extensor type.

The faradic contractility of the muscles is unimpaired; occasionally it is increased rather than diminished. The muscles do not undergo atrophy except by disuse. The temperature of the paralysed limbs, which at first is usually increased, is generally found to be lower than that of the sound side, to the extent of a degree, more or less.

Recovery may take place from all the symptoms of this stage, within a period varying from weeks to months, or the patient may pass into the third stage.

Third stage.—The special symptoms of this stage are the occurrence of what is termed 'late rigidity' in the paralysed limbs, a condition of evil import. This rigidity shows itself most frequently in the arm, but it is common enough in both limbs. The rigidity affects the flexors more particularly, and causes the limb to assume a position in which flexion predominates. It is variable in degree, and at the commencement is capable of being overcome. At first, also, it is remittent, tending to give way when the patient abstains from volitional efforts or from excitement, and seems almost gone on waking from sleep or when the patient yawns or stretches himself. Gradually it assumes a more intense form, and the limb becomes permanently fixed and rigid.

After death, this condition is found to coincide with descending sclerosis of the motor tracts of the brain and spinal cord. The degeneration proceeds from the seat of lesion downwards through the

crus, pons, and pyramid of the same side, and then across to the posterior part of the lateral column of the spinal cord on the paralysed side. Frequently, also, a similar track of degeneration is found on the inner aspect of the anterior column of the spinal cord, and occasionally also in the lateral column on the same side as the brain-lesion.

Even during the rigid stage there is, as a rule, no trophic degeneration of the muscles or annihilation of faradic contractility, though the muscles waste from disuse unless artificially stimulated. But in some rare instances, as Charcot has shown, the secondary degeneration invades the anterior cornua of the spinal cord, in which case amyotrophy or trophic degeneration of the muscles ensues.

There is no recovery from this condition.

Variations and complications.—Though hemiplegia of the opposite side, without affection of sensation, is the type of disease of the internal capsule, certain variations from the above type are not uncommonly observed.

When sensation is permanently affected along with voluntary motion, we have reason to regard the lesion as implicating the posterior part of the internal capsule and the optic thalamus, an occurrence by no means rare. Co-existing with hemianæsthesia is usually homonymous hemianopsia from interference with the adjacent optic radiations. When, however, the lesion causes rupture of the fibres forming the anterior two-thirds of the posterior limb of the internal capsule, the hemiplegia is most marked and most enduring. It is this lesion only which gives rise to secondary degeneration of the motor tracts and permanent rigidity.

Cases are on record in which lesions of the internal capsule have given rise, not to complete hemiplegia of the opposite side, but to monoplegia, such as paralysis of the face or of one or other limb. These monoplegiæ are due to limited lesions of the internal capsule, which the researches of Franck and Pitres, Beevor and Horsley, and others have demonstrated, contains the motor tracts corresponding to the differentiated centres of the cortex.

The arrangement of the tracts in the internal capsule is briefly as follows. In the fore part of the anterior limb are the corticofugal and corticopetal fibres of the frontal lobe. In order from before backwards there come the fibres for the conjugate movement of the eyes, the mouth and tongue, then the face, the upper limb, and the lower limb. Posteriorly is the combined sensory tract extending as far as the hind end of the lenticular nucleus.

D. FERRIER.

W. A. TURNER.

INTERNAL EAR, Diseases of.—*See* EAR, Diseases of.

INTERSTITIAL (*inter*, between; and *sto*, I stand).—Relating to the interstices of an organ. The term is applied to the tissue which exists between the characteristic elements of any organ, namely, to some form of connective tissue.

INTERTRIGO (*inter*, between; and *tero*, I rub).—**SYNON.**: Erythema intertrigo; Eczema intertrigo.—**DEFINITION.**—A slight erythematous inflammation of the skin occurring in the hollows or folds of the integument, where two surfaces lie in apposition.

ÆTIOLOGY.—The cause of intertrigo is not, as might be implied by its name, *friction alone*; but

rather moisture and heat associated with contact and pressure, acting on a sensitive skin. In certain situations the amount of inflammation is liable to be aggravated by the addition of irritant discharges, such as excessive perspiration, decomposed urine, and fecal matter.

Intertrigo is common in corpulent persons, in those in whom there is free activity of the sudoriparous glands, and in infants from inattention to the napkins. In infants it is seen in the perinæum, extending from the anal fossa behind to the groins in front, and likewise in any other of the deep folds of the integument, as the folds of the neck. Among adults, in addition to these situations it occurs in the axillæ, in the groove beneath the mammae, between the thighs, in the genital regions, scrotal and labio-femoral clefts, the cleft between the nates, and in the flexures of joints; between the glands and the prepuce; at the vulva, and in obese women over the iliac crests. It is well to keep in mind the possibility of inherited syphilis.

The term intertrigo points to a rubbing together or chafing, fretting or galling of the skin by friction, and no doubt friction may have some share in producing the inflammation; but it is also certain that intertrigo results most frequently from irritation caused by the heat and moisture of the part.

DESCRIPTION.—Intertrigo very rarely remains at the erythematous stage, having a natural tendency to run on to exudation, and to be further complicated with excoriations and chaps. In this condition it becomes an eczema (eczema intertrigo), and is very properly treated as such. Many cases beginning as a simple intertrigo drift into a distressing pruriginous eczema, and not infrequently a mild phase of eczema seborrhoicum is the starting-point. Heat, tenderness, and frequently pruritus are the usual sensations.

TREATMENT.—The removal of the cause is the first indication to be attended to in the treatment of intertrigo. This may be effected by keeping the folds of skin apart by thin folds of absorbent borated gauze or silk. The parts should be kept scrupulously clean, dry, and as cool as possible, and dusted with any impalpable unirritating desiccative powder, as fuller's earth, French chalk, kaolin, starch, zinc oleate, zinc oxide, boric acid, or lycopodium. Various combinations of these may be tried, and a little powdered camphor may be added for its antipruritic effect. The 'caking' of starch-containing powders is a great objection to their use. Pruritus must be combated by appropriate measures, and decomposition of secretion guarded against. Where powder is unsuitable, a lotion of lime-water thickened with oxide of zinc will be found useful; or a weak lactate of lead lotion may be tried; or zinc ointment should be kept constantly applied. Where there is much exudation, it is desirable, as in eczema, to avoid abluion and ring the changes with powders, stiff ointments, or zinc-gelatin paste or creamy lotions according to the changing conditions of the affection.

JOHN HAROLD.

INTESTINAL OBSTRUCTION.—**SYNON.** : *Ileus*; *Fr.* *Occlusion Intestinale*; *Ger.* *Darm-verschlussung*.

DEFINITION.—Under this term are included all those cases in which the contents of the intestinal canal are obstructed in their onward passage, by conditions occurring within the abdomen or pelvis. Cases in which obstruction is due to conditions

affecting bowel protruding through one of the external openings are included under the head of **HERNIA**.

The subject of intestinal obstruction will be best treated by first discussing *the condition in general*, and afterwards *its different varieties* in detail.

ÆTIOLOGY AND PATHOLOGY.—The causes of intestinal obstruction may be enumerated as follows, arranged as nearly as possible according to the acuteness and urgency of the symptoms and the imminence of danger to life to which they give rise. The relative frequency with which they occur may be approximately estimated by the numbers appended, representing the results of an analysis of 1,839 fatal cases.

1. *Strangulation by Bands or in Apertures* (440).

(a) By peritoneal bands, the results of previous inflammatory mischief, either under such bands, or by loops or knots, or in buttonhole-like slits, or by kinking caused by traction, or by the margins of slits and rings produced by the adhesion of organs to one another, or to some part of the parietes (219). (b) By the omentum or mesentery forming bands or slits. (c) By diverticula or diverticular cords, due to the persistence of the vitelline duct (Meckel's) or of the omphalo-mesenteric vessels, free or attached (75). (d) By the appendix vermiformis (42). A Fallopiian tube adherent to the neighbouring peritoneum is another cause of strangulation by a normal structure abnormally attached. (e) By the margins of peritoneal pouches (retro-peritoneal hernia, hernia through the foramen of Winslow, and other forms of internal hernia) (39). (f) By bands resulting from inflammation about the necks of old herniæ. Another instance which must be remembered is the band which may be formed by the pedicle of an ovarian cyst.

2. *Volvulus*.—In some cases the intestine is obstructed by being twisted on its mesenteric axis or even on its own axis. In others, the lumen of the sigmoid flexure may be closed by its being twined round a loop of ileum (106).

3. *Intussusception or Invagination* (537).

4. *Impaction of Gall-stones* (51).

5. *Contractions*.—Under this term—the 'contraction' of Fagge, the 'compression and traction' of Bristowe—are included those cases in which the bowel is gradually obstructed by matting together of its coils. This may be due to knitting together of one or more coils by peritonitis, originating, for example, in inflammation of the mesenteric glands. Other conditions are given below.

6. *Stricture*.—(a) Cicatricial, from injury or ulceration; (b) new-growths (373).

7. *Compression*.—By new-growths, hydatids, &c., outside the bowel (66).

8. *Impaction of Foreign Bodies, or Intestinal Concretions* (78).

9. *Impaction of Fæces. Confirmed Constipation* (78).

10. *Congenital Malformations*.

SEATS.—Some parts of the intestinal tract are very much more frequently affected by certain particular causes. Thus, acute obstruction by bands most frequently affects the small intestine; volvulus, the sigmoid flexure. Intussusception most frequently involves the cæcum and colon, and, next, the ileum. Constrictions due to new-growths are most common in the large intestine, especially in its lower portion. Impaction of gall-stones, with very few exceptions, occurs in the lower part of the

ileum. Contractions and traction affect the small intestine more frequently than the large.

SYMPTOMS AND SIGNS.—The symptoms and physical signs of intestinal obstruction are, as a rule, sufficiently constant and characteristic to establish the general diagnosis. But it is usually very difficult, and often impossible, to determine without exploration the differential diagnosis.

The symptoms and signs common to intestinal obstruction will be first given, and then, more briefly, those specially characteristic of each form.

1. *Pain.*—Cases of acute obstruction by a band, volvulus, many intussusceptions, or impaction of a gall-stone, are usually signalled by acute pain, often 'doubling the patient up,' and sometimes producing faintness and collapse. Where there has been a period of incarceration, as in some cases of obstruction by bands or in slits, pain supervenes somewhat more gradually, though later it becomes equally severe. In stricture of the large intestine there is, in the earlier stages, comparatively little pain. Again, in obstruction of the large intestine by impaction of feces, the patient complains merely of fullness, weight, and discomfort.

At the onset the pain is doubtless due to the injury immediately inflicted on the serous and mucous coats, and is very speedily increased and maintained by the effects of the congestion of the blood-vessels on the nerves. This pain will obviously be more severe when the small intestine, with its more intimate association with the nerve-centres and its larger vascular supply, is affected. But it must always be remembered that the severity of the pain depends on the abruptness and completeness of the obstruction, and the extent to which the intestine is involved, rather than upon the variety and cause of the obstruction. Somewhat later comes the pain associated with distension of the bowel itself; this is increased at intervals by paroxysmal exacerbations of acute suffering, which accompany the futile peristaltic efforts of the intestine. Instances of this pain are only too well seen in patients with thin abdomens, in whom attacks of peristalsis, especially when the muscular coat has become hypertrophied, recur after the taking of food, examination of the abdomen, the administration of an enema, &c. Other causes of pain are traction upon inflamed parts, especially when ulceration is beginning to set in; and, at a later stage, enteritis and peritonitis.

With regard to the constant or spasmodic nature of the pain—when the obstruction is complete the pain is constant, with periodic exacerbations; but with an incomplete obstruction it is likely to be intermittent. An important point to consider is how far the pain affords any guide as to the situation of the obstruction. In the great majority of cases of acute intestinal obstruction, wherever may be the seat of the mischief, the pain is referred to the neighbourhood of the umbilicus (*see PAIN IN VISCERAL DISEASE*). Thus, in a large number of cases the site of the pain is of little value as a guide. But there are certainly some cases, especially those of acute obstruction by bands, or sudden strangulation in a slit, in which the pain is referred to a region other than the umbilical. Where the pain is accompanied by the occasional uprising of a coil of intestine anywhere, this spot will very likely be a guide to the seat of the mischief. The readiness with which pain may be masked by preparations of opium, and the dangerously fallacious appearance

of improvement which may follow; the way in which the distinct localised suffering of obstruction may be merged and lost in the more general and diffused pain of peritonitis; and, finally, the cessation of pain which may occur at the close, when the nervous system is dulled by impending death—need only be alluded to here.

2. *Tenderness.*—Both in acute and chronic obstruction, tenderness is usually absent until peritonitis has supervened.

3. *Vomiting.*—This is a very constant symptom of intestinal obstruction. It may commence almost simultaneously with the occurrence of the obstruction, in which case it is due to the shock of the injury inflicted. This vomiting, and its characteristic features—first the contents of the stomach, then bilious fluid, and lastly, liquid more or less feculent—have been differently explained. It is undecided how far the obstruction causes the usual peristalsis to be reversed (anti-peristalsis), or how far, aided by the distension of the bowel above and the glandular secretion poured out, it converts the usual passage of intestinal contents into two currents—one, peripheral, in the natural direction up to the point of obstruction, and the other central or axial, which pours the intestinal contents into the stomach. As a general rule, the higher the seat of obstruction, and the more acute the cause, the more severe is the sickness, and the more frequently does it recur. When the obstruction is high up in the small intestine, the vomit is usually bilious and offensively sour, but without the foetor of feces. When vomit has been retained for any time, as when the patient is under the influence of opiates, it may have had time to decompose and to acquire a feculent odour (Treves). Again, true stercoraceous vomit may come from the lower ileum as well as from the colon, for the contents of the lower ileum may, in the natural state, have all the characters of feces. Moreover, great distension of the intestine may render the ileo-cæcal valve inefficient to prevent regurgitation from the large into the small intestine.

4. *Constipation.*—This may be absolute from the first, even to the passage of flatus, in acute complete intestinal obstruction, as in that due to bands, apertures, volvulus, or gall-stone.

In other cases, where the strangulation is less abrupt and severe, or where the intestine by some peristaltic movements frees itself for a time, fecal evacuations may be passed for a while; and a careful inspection of these, especially as to presence of bile, consistency, feculent odour, &c., may give valuable information as to the degree and seat of the obstruction. In intussusceptions, especially in the more chronic cases, the bowel is rarely altogether impermeable at first, though later it becomes so from the effect of inflammatory swelling. In such cases there is a period in which small quantities of fecal matter mixed with blood and mucus are passed, frequently with much tenesmus; later on blood and mucus only are passed. In strictures of the bowel, constipation comes about comparatively slowly, being here replaced by irregular actions, diarrhoea alternating with constipation, the motions being sometimes altered in shape and size, with passage of blood, &c. Later on, constipation may be rendered absolute by impaction of some undigested article of diet, or by a twist or kink of the bowel above the obstruction.

First among the causes of constipation comes occlusion of the bowel. Another very important

one is reflex nerve-action. Thus, in cases of acute strangulation, the constipation is often absolute from the very commencement, although the obstruction may be in the small intestine, and much fecal matter may still be lodged below the point of occlusion. Again, constipation is very usual in those cases of partial obstruction of the bowel where a segment is suddenly and severely nipped. This is well observed, as a rule, in Littre's hernia, where only a part of the circumference of the bowel is involved in the strangulation. Another cause of constipation which must be remembered is paralysis and exhaustion of the intestinal wall.

The following fallacies must be borne in mind. Even after complete occlusion has occurred there may remain in the bowel, below the seat of obstruction, some portion of its contents; and the secretions of the mucous membrane being added, the evacuation of these by natural effort, aided by enemata, may give rise to the false idea that the occlusion is not complete, or that relief has been obtained. Again, the bubbling away of an enema must not be mistaken for the passage of flatus. Finally, false hopes are sometimes raised by the passage of a stool shortly before death. If this has come from above the obstruction, it may be due to some sloughing which has taken place or relaxation of spasm.

5. *Aspect and condition of the abdomen: Distension, swelling, meteorism.*—The degree of distension and its rate of onset vary with the cause and site of the obstruction, the amount of vomiting, the food taken, &c. Thus, in acute obstruction of the lower part of the ileum, distension comes on rapidly and severely; but an even more rapid and a severer distension is seen to follow on one form of obstruction of the large intestine, namely, volvulus. In obstruction high up in the ileum or jejunum, the epigastric and upper regions appear distended, and the lower ones sunk. But in trying to diagnose the site of the obstruction from the distension the greatest caution must be maintained. 'There is a difference in the shape of the abdomen when distended, according as the arch of the colon is below or above the seat of obstruction. In the former case the belly is rounded, projecting well forwards, but with comparatively little fulness of the lateral and lumbar region. In the latter case it is more broad, and, if the hand be placed on the patient's loins as he lies in bed, a feeling of resistance is experienced which is wanting when the small intestine is alone distended' (Fagge). But the same writer gives us the following cautions in interpreting signs. Absence of fulness in the course of the colon is no absolute proof that the disease is high up in the intestine. Again, the presence of fulness in the course of the colon is no proof that the seat of the obstruction is in the large intestine. For in more than one instance a prominence of the epigastrium and the appearance of a large horizontal coil have been due, not to the transverse colon, but to the ileum, dilated until it rivalled the colon itself. The presence of meteorism is, when rapid and severe, most dangerous and distressing.

Apart from the above distension from accumulation of intestinal contents, certain localised swellings in the abdomen may be occasionally recognised. Thus, intussusception commonly gives rise to an elongated sausage-shaped swelling lying in the course of the large intestine. Stricture of the sigmoid flexure may sometimes be felt in a patient

with a thin, relaxed abdominal wall, as an indistinct localised thickening. Other instances of tumour are very rarely met with. The fat-loaded abdominal wall usually present in a sufferer from impacted gall-stone often prevents this cause of obstruction being felt by palpation. A localised swelling will be of more value as a guide if pain has also been referred definitely to this same particular spot. A number of coils of small intestine, matted together by adhesion, may form a kind of tumour, and localised dullness on percussion has been caused by collapsed coils of small intestine grouped together below an obstruction (Treves).

6. *Peristalsis.*—The fact that the movements of the intestine can be clearly recognised in some cases may be of much help in the diagnosis. One coil may be seen rising up and becoming prominent, and then sinking down and giving place to another, and sometimes waves of action, as it were, seem to pass along a considerable length of bowel. Such movements recur at irregular intervals, and are accompanied by gurgling noises (borborygmi) and sensations, and by exacerbation of suffering. This peristalsis, as Fagge pointed out, is characteristic of the chronic varieties of obstruction, in which the coats of the bowel have undergone hypertrophy. It also indicates an absence of peritonitis. While peristaltic movements are much more often seen in the small than in the large intestine, they may sometimes be observed in the latter. Fagge also pointed out, as worthy of especial note, that the large intestine, when distended, does not continue to lie horizontally across the upper part of the abdomen, but bends downwards, and may form a broad loop, lying vertically and (with the dilated ascending and descending colon) filling the whole front of the abdomen. On the other hand, the coils of the ileum are, under similar circumstances, generally arranged transversely; and, as these coils are often quite as broad as the transverse colon, the uppermost one, lying horizontally just below the ribs, may easily be mistaken for that part of the large intestine.

7. *Diminution of Urine.*—In acute obstruction the urine is diminished in quantity. This fact has been differently explained. Some writers consider that it points to a site of obstruction high up in the jejunum, the area for the absorption of fluid being thus much diminished. Others attribute it to the urgency of the vomiting which occurs in acute obstruction high up. Others again argue that this symptom is merely one of the phenomena of collapse, and will occur in all forms of intestinal obstruction, whatever their seat, in which collapse is present; and as collapse is often present in obstruction of the small intestine, while it seldom occurs in that of the large bowel, suppression or diminution of urine is common in the former, and rare in the latter, condition.

8. *General Aspect and Symptoms.*—In cases of acute obstruction, often from the first, and in the later stages of both acute and chronic obstruction, the general aspect of the patient is more or less characteristic. A condition of collapse frequently occurs; and when this appears early it is due to the shock of the injury, and is usually proportionate to the nerves and the amount of intestine involved, being more marked in the case of the small than of the large intestine; and, above all, to the abruptness and severity of the obstruction. The countenance is expressive of anxiety and distress; the eyes

are sunk, often with dark circles round them, the nose pinched, the cheeks hollow, the lips pale or purplish, and the complexion faintly livid; the general surface is cool or cold (the ears, forehead, nose, and feet first becoming cold), and often covered with a clammy perspiration. Although the mental faculties are as a rule undisturbed, there is a disposition to torpor, from which the sufferer is from time to time aroused by exacerbations of pain, or recurrence of vomiting. The pulse is frequent and small, and towards the end becomes thready. The temperature is rarely above normal unless peritonitis sets in; usually it is normal or subnormal, sometimes falling to a marked extent. Sometimes there is more or less dyspnoea, which may be explained in part by pressure upwards of the diaphragm by the distended bowel below, and the latter cause often gives rise to distressing hiccough. The voice varies, being feeble and whispering, or strong and full quite up to the end. The tongue becomes red, and later dry and brown. Towards the close there is often a combined odour of offensive sweetness and decomposition in the breath. The patient suffers from severe and constant thirst, which often he fears to assuage lest vomiting should be provoked.

In most cases the course is one of progressive emaciation, weakness, and exhaustion, the end being often preceded by peritonitis.

COURSE, COMPLICATIONS, AND TERMINATIONS. In the acute forms of intestinal obstruction the prospect of recovery is extremely slight; perhaps, in the large majority of cases, it would be just to say that there is none at all. And here a word must be said as to those extremely rare instances of spontaneous recovery which have occurred from time to time under every form of acute obstruction, volvulus only excepted. Very much of the value of these cases has been lost by their after-histories not being published, chances thus being lost of our knowing in what cases of really mechanical obstruction spontaneous recovery is really possible. In the second place there is strong reason to believe that in several of these cases the diagnosis has been at fault, the real cause of mischief being peritonitis, e.g. starting from the cæcum or its appendix, or one originating in tubercular mischief, an enteritis, and not mechanical obstruction.

In the more chronic forms of obstruction, with the exception of those depending upon impaction of feces, and some others, perhaps (as chronic intussusception), death, though considerably longer delayed, ensues sooner or later, in spite of temporary relief afforded by operative measures or in other ways.

In cases of acute strangulation, in which the occlusion has been sudden and complete from the first, and in which timely relief has not been obtained, the average duration has been found to be from three to six days. In the cases reported as fatal within a few hours, it is possible that the case has been one of perforation of the intestine or stomach, rather than one of obstruction of the bowels (Fagge). Where the case is one of incarceration at first, followed by actual strangulation, death may not occur until after the lapse of eight or ten days. In cases of constriction or compression in which complete occlusion has come about gradually, or even has not been finally established, the duration of life varies greatly according to the complications which arise, and it may be prolonged for weeks or even months. So, too, in cases of stric-

ture of the large intestine, where the patients are of average intelligence, when they avail themselves regularly of medical supervision, and are amenable to the directions given, especially in the matter of diet, the end may be deferred for one and a half or two years or more.

The *complications and accidents* that are liable to occur are: Peritonitis starting from the seat of the lesion, and more or less rapidly spreading and becoming general; enteritis; ulceration and perforation of the bowel; sloughing of the strangulated or intussuscepted portions; hæmorrhage into the peritoneal cavity or into the bowel; sudden asphyxia or broncho-pneumonia, due to the entrance of vomit into the air-passages; absorption of the products of decomposition or of the breaking down of a growth; gradual asphyxia from the interference with respiration by abdominal distension; and syncope from cardiac depression and cerebral anæmia.

DIAGNOSIS.—Nowhere does successful treatment depend more intimately on correctness of diagnosis; nowhere is a correct diagnosis more invariably difficult; nowhere is it so often impossible. We can only hope to arrive at it by careful attention to the following points, and by striving to keep before us a mental picture of the different hidden possibilities which may lie at the root of the mischief.

The following questions must be considered: I. *Is the obstruction acute or chronic?* II. *Where is the obstruction situated?* III. *What are the best methods of investigation?* IV. *What are the diseases most likely to be mistaken for intestinal obstruction?* V. *Is the case one favourable or unfavourable for operation?* This last question will be considered later under **TREATMENT**.

I. *Is the obstruction acute or chronic?* The symptoms given as distinctive of the two groups are often misleading when applied to individual cases.

(1) Under **acute obstruction** would be included the following: (a) Strangulation by bands or through apertures; (b) volvulus of the colon; (c) acute intussusception; (d) impaction of a gall-stone in the small intestine.

SYMPTOMS.—Pain, whether agonising or colicky, sets in suddenly at a definite time, being generally referred to the neighbourhood of the umbilicus. It is usually paroxysmal at first, but tends to become continuous. It may have followed an unwise meal, going to work, some straining effort, active purgation, or a blow. Vomiting is early and severe—first the contents of the stomach—then bilious, excited by any effort to take food—and ultimately brownish, foul-smelling, or more completely stercoraceous. Constipation is absolute, even to the passage of flatus, though small scybalous masses may come away from a point below the obstruction after enemata or straining efforts of the patient. The abdomen soon becomes distended, but its form presents little that is really distinctive of one form of obstruction rather than another; this being largely due to the facility with which one or two distended coils may be displaced into areas where they conceal the proper contents, and simulate their distension. The urine is diminished or suppressed. The collapse, the state of the tongue, pulse, and temperature are as already stated.

(2) Under **chronic obstruction** would come: (a) Stricture of the large intestine; (b) contractions or adhesions obstructing the intestine (usually small) by bending, dragging on, narrowing, or matting up

one or more coils; (c) stricture of the small intestine after ulceration—traumatic, tubercular, or malignant; (d) chronic intussusception; (e) obstruction by compression of growths from outside; (f) faecal impaction.

SYMPTOMS.—In chronic obstruction these are characterised by their slow irregular development. The pain comes on at first at long intervals, corresponding to troublesome attacks of constipation, and is put down to 'attacks of wind,' colic, or indigestion. Even late in the case fixed pain is often absent; but pain occurs in paroxysms which correspond to attacks of peristalsis, showing the writhing movements of intestine, with muscular coats hypertrophied and as yet not stilled by peritonitis. Constipation is for some time the chief trouble: the bowels never act satisfactorily without aperients. Constipation alternates with diarrhoea; or broken up or narrowed bits, unsatisfactory alike in form and bulk, are passed with difficulty, accompanied by much flatus and some loose motion. After one or more attacks of obstruction more or less complete, the contracted lumen of the bowel may be absolutely blocked. Vomiting is often long deferred, and the patient may keep comparatively well (with clean tongue, sleeping well, and taking food), even when his condition has become one of great danger.

While the above description applies to well-marked acute and chronic obstruction respectively, the two forms do not always fall into such distinct groups. Further, the above terms do not always correspond to obstruction of the small and obstruction of the large intestine. All the symptoms of chronic obstruction, lasting over six months, may be presented by a case of obstruction of the ileum from cancerous puckering of its mesentery; while, on the other hand, every symptom of the acutest obstruction of the small intestine, ending fatally in four days, may be shown by a volvulus of the sigmoid (Fagge). Again, the greatest difficulty in deciding between acute and chronic obstruction may be caused by a patient, whose age suggests malignant stricture of the large intestine, and in whom absolute constipation, a greatly distended belly, and evident peristalsis call loudly for relief, definitely declaring that the constipation is merely a matter of a few days, and denying absolutely any previous attacks of constipation or obstruction. Finally, there is a third class in which an attack of acute obstruction supervenes upon symptoms indicating a chronic obstruction. Such condition most frequently occurs in patients with malignant stricture, or with coils matted together by adhesions, with chronic intussusception, or gradual occlusion of the lumen of the bowel by a growth within or outside its walls, the actual obstruction being brought about by some sudden blocking, as by a faecal mass, or by kinking or bending of the bowel above. The chief help in the diagnosis is given by examination of the patient's history. There will usually be an account of symptoms pointing to chronic obstruction, with previous less severe attacks.

II. Where is the obstruction situated?—It may be said at once that a case of chronic obstruction is usually one of the following: (a) Stricture in the rectum, sigmoid flexure, splenic or hepatic flexure; (b) stricture of the small intestine from mischief within its lumen, or from matting, kinking, or dragging on it by adhesions, &c., outside; (c) chronic intussusception; (d) faecal impaction. Of the above, ob-

struction of some point in the left side of the arch of the large intestine is by far the most frequent.

With regard to acute obstruction, usually in the small intestine, it must be confessed that it is very frequently quite impossible to go beyond localising it in the small intestine. It has been shown that the urgency of the chief symptoms is not related to the seat of the obstruction, but to its severity. No doubt obstruction high up in the small intestine will in many cases be accompanied by earlier vomiting, but less likely to become faeculent. Distension of the abdomen will be less in a case like the above than in one where the obstruction is low down in the ileum. The numerous fallacies which may beset us, depending on the amount of food taken, the influence of drugs, the erratic manner in which one or two coils may cause distension of an area at some distance from their proper habitat, must be borne in mind. It will be wiser to be content in acute obstruction with determining whether it is in the small intestine, as by a band; in the large, as in volvulus; or in both, as an acute intussusception—and to remember that all beyond may be blind guesswork.

III. What are the best methods of investigation?

A correct diagnosis can often only be arrived at by most careful attention to the following points. Trivial as some may seem, all or any may be of the utmost importance; and as cases of acute obstruction may vary every hour, repeated careful examinations may be needful to throw light on a condition which was quite obscure a few hours before.

(a) *The History.*—The value of this is often nil, but the smallest point may sometimes be of the greatest importance. Thus (i) *previous peritonitis* may lead to a suspicion of strangulation by a band, or by multiple adhesions. The history of pelvic mischief, especially in women, or of tubercular inflammation may be of the utmost value. (ii) *Injury*, such as a kick from a horse, may have led to a rupture and subsequent hole in the omentum, thus causing later on a seat of strangulation; or to obstruction from cicatrisation of some bruised loop of intestine. (iii) *An imprudent meal* of heavy and indigestible food may determine the occurrence of obstruction, by the sudden formation of gas and turbulent peristalsis in cases of peritoneal adhesions, or stricture, by causing twisting or kinking. (iv) *Old-standing hernia.* Adhesions formed about the neck of an inguinal hernia may strangle a loop of small intestine quite independent of the hernia.

(b) *The Symptoms.*—These are next to be investigated. The symptoms characteristic of acute and chronic obstruction respectively, and their fallacies, have been already given.

(c) *Physical Examination.*—The most careful and thorough examination of the abdomen by palpation and percussion, and by exploration of the rings, the rectum, and, if need be, the vagina, should be instituted at the earliest practicable period, before general abdominal distension or the supervention of complications has obscured the indications first presented. The form of the abdomen is to be first studied. Then, any fulness which remains localised, especially if accompanied by abiding pain in the same place, any limited dulness, any repeated upspringing of one or more coils at the same place (especially if it is noticed that borborygmi are arrested here), may all be of value in helping to localise the seat of obstruction. In some cases it may be desirable to administer an anæsthetic, to facilitate the examination by relaxing the abdominal

muscles, and to save additional suffering. But this step may be dangerous if vomiting is easily excited. With regard to the rings, the regions of umbilical, inguinal, femoral, and even obturator hernia should be carefully scrutinised. Not only may the modesty of a patient have led to the concealment of an ordinary hernia, but possibly a small knuckle may be tightly strangled in the neighbourhood of the internal ring, or in the canal, or the lumen of a piece of intestine may be partially closed in a tiny femoral hernia. As to the need of a rectal examination, it is only too certain that even nowadays this method of examination is still too much neglected, and thus intussusceptions are sometimes overlooked until it is too late to reduce them by insufflation; and cases of malignant stricture are allowed to go on, and treated as indigestion, flatulence, or constipation. The introduction of the whole hand into the rectum has been rightly given up of late years; the information it gives is very limited, and only obtained at grave risk. Exploration *per vaginam* may afford additional information.

(d) *Use of Enemata and the Long Tube.*—These methods are usually as useless in diagnosis as in treatment. Further, their use is often accompanied by danger, and may be misleading also. Finally, they frequently weaken and distress the already sufficiently handicapped patient. The following dangers and fallacies accompany their use: (i) An obstruction may be pervious to fluid from below and not from above (Fagge). In such a case the fluid pumped through may easily add to the accumulation above this point. (ii) When the abdomen is distended, the administration of large enemata must add to the misery of the patient. (iii) Further, the passage of an enema tube and the amount that can be injected may be misleading also. Thus, it is well known that the tube may be stopped by a fold of mucous membrane; or it may double on itself, thus leading to the belief that no obstruction exists within reach. Again, it is obvious that the sources of fallacy—leakage, admission of air, the varying capacity of the large bowel in different patients, &c.—are numerous. The use of enemata will again be alluded to under TREATMENT, p. 780.

IV. *What are the diseases most likely to be mistaken for intestinal obstruction?*—Of these, the most important in frequency and gravity is peritonitis—especially that form due to mischief in the cæcum or the appendix, or a peritonitis of tubercular origin. Pain, vomiting, constipation, and tenderness may all be present and lead to the greatest difficulty in diagnosis. The points most likely to help are the following: (1) *The previous history.* Thus, though the onset may appear to be sudden, there will very likely have been attacks of 'stomach-ache,' irregular action of the bowels, and tenderness in the right iliac region. (2) *The temperature.* This is usually high in acute peritonitis; but, unless the case is seen early, it may be, as in intestinal obstruction, inclined to subnormal if prostration or collapse have set in. (3) *The vomiting* is usually less urgent in peritonitis, and more rarely feculent. (4) *The constipation* is less absolute. (5) There is usually diffused tenderness and distension in peritonitis. (6) There is no peristalsis. (7) *The abdomen* in peritonitis is often 'smooth, firm, and barrel-like' (Hutchinson). Other conditions occasionally simulating intestinal obstruction are enteritis, e.g. from eating tinned foods, and ptomaine poisoning; acute hæmorrhagic pancreatitis: here

the suddenness of the onset, the rapid collapse, and perhaps the presence of a median deep-seated epigastric swelling, may suggest the cause; thrombosis of the mesenteric artery is another condition which, by the abdominal pain, vomiting, and tympanites, simulates obstruction, but here diarrhoea and blood-tinged stools are not unknown; lead-colic, again, has to be remembered as a condition bringing about an arrest of action but not mechanical obstruction, and to be distinguished by the history and progress of the case.

TREATMENT.—This will be divided into A. Non-Operative, and B. Operative. But while the first will always maintain its place in cases where an operation is refused, where the condition of the patient or his surroundings and those of the medical man do not admit of its performance, it cannot be too strongly laid down that the only hope in acute intestinal obstruction lies in operation, both for clearing up the diagnosis, and for relieving the condition which will otherwise certainly prove fatal. But while the adoption of non-operative treatment in acute intestinal obstruction is almost certainly doomed to failure, it does not therefore follow that operative interference will meet with a large amount of success. Any candid, reflective mind, which has made itself acquainted with the facts of the case, will admit that the same brilliant success which modern surgery has obtained in several regions of the abdomen has not extended to intestinal obstruction, especially the acute variety. The reasons are not far to seek. We have to deal here with conditions often most difficult to find, with conditions that quickly produce irreparable mischief, conditions which early exhaust the patient's strength, and in the exploring and removing of which grave shock is, of necessity, often produced. The diagnosis of acute intestinal obstruction having been made, the practitioner will do well to put both sides before the patient and his friends, the uselessness of palliative treatment, the risks of operative interference, and the fact that these risks are much increased by every hour's delay. If the facts of the case permit of one of those varieties more favourable for operation being diagnosed, such as a Meckel's diverticulum, a single band, or an early intussusception, the practitioner will be justified in strongly urging operative interference. When the case is more obscure, he can only put both sides fairly, and leave the decision to others.

A. NON-OPERATIVE TREATMENT.—I. *Purgatives.*—As a rule almost without exception, in acute or subacute cases, the use of all kinds of purgatives is to be emphatically condemned. They aggravate symptoms; while they are liable to light up quiescent into acute trouble, and convert chronic mischief into acute. Threatening sloughing or perforation may also be rendered inevitable. It is only where all urgent symptoms have subsided, or, in more chronic cases, where there is no evidence of peristalsis or of peritonitis, that mild laxatives, especially some salines, often prove of great value, but great caution is necessary in their administration. These points, together with the use of stronger aperients in obstruction from fecal impaction, will be alluded to later.

2. *Sedatives.*—Opium and belladonna have been given far too much as a matter of routine, as in the usual combination of opium gr. $\frac{1}{2}$ -gr. 1, and green extract of belladonna gr. $\frac{1}{6}$ -gr. $\frac{1}{4}$, every three or

four hours. But it must be remembered (1) that our knowledge of the action of these drugs on the inhibitory and accelerating nerves of the intestine is by no means complete. (2) That we are here especially in the dark. Thus, if we could tell the nature of the obstruction, how the coils lay, and which of them were capable of usefully directed peristaltic action, we might perhaps employ belladonna in large doses. In other cases, where ulceration might be threatening, opium alone would be employed. (3) That while opium undoubtedly allays the pain, checks violent and hurtful peristaltic movements of the intestines, dulls the acuteness of the patient's mind constantly alive to his anxieties and distress, while it promotes sleep and thus husband his strength, it is an entire mistake to speak of opium by the often-quoted phrase 'as our sheet-anchor' in intestinal obstruction. It may dangerously modify symptoms and signs; thus, a patient dosed with opium may be quite unaware that the tenderness of his abdomen is increasing. It may apparently so improve the condition that an operation, later on proved beyond a shadow of a doubt to have been the patient's only hope, is put off till it is too late. In other words, while symptoms are lessened, the condition of the intestine may be hourly getting worse. (4) Adult patients often show remarkable susceptibility to belladonna; and the excitement which may follow an over-use of this drug in these cases may be most harmful to the patient. (5) If opium and belladonna must be given we should be content with the smallest possible doses, especially of the former. In other words, the patient must be judiciously prescribed for, and not drugged. Later on, when operation is declined or set aside, it may be needful to give opium in larger doses, especially if peritonitis be present. (6) There is a certain class of adult cases of intestinal obstruction in which belladonna, in much larger doses than are usually tried, has been most successful. Thus, in more chronic cases, one or two grains of the green extract given every hour, till from five to fourteen grains have been taken, have been followed by relief.

The subcutaneous injection of morphine and atropine in the smallest possible doses is to be preferred to the routine treatment by opium and belladonna. Their administration by suppository is the least satisfactory of all methods in cases of acute obstruction. In a few very acute and painful cases the inhalation of an anæsthetic may be asked for; it must always be remembered that this course, while temporarily relieving suffering, and perhaps enabling the case to be further cleared up, has certain inherent dangers of its own.

3. *Diet*.—Sufficient care is still but seldom taken in this simple matter, and the patient is allowed to add needlessly to his misery and danger. In acute obstruction, whenever the diagnosis is suspected or established, it is much best to cease feeding altogether by the mouth, and to trust to nutrient enemata. The small intestine and the stomach itself are liable to be gradually filled up by an ascending column of fluid, and vomiting is thus constantly impending; and when it has already set in, it is only made worse by giving food by the mouth. As a rule, nothing whatever should be given by the mouth save a little ice in small pieces. Nutrient enemata may be made on some such plan as—milk $\mathfrak{z}\mathfrak{j}$, brandy \mathfrak{zss} ., yolk of one egg, with liquor pancreaticus (B.P.) $\mathfrak{z}\mathfrak{j}$, or a few drops of

diluted hydrochloric acid and a little pepsin—the whole being gently warmed, but not cooked. Simple enemata of strong beef-tea, only just liquid, may be given every two, three, or four hours. After, or in place of either, a nutrient zymised suppository may be inserted. Before an enema is given, it must be ascertained that the rectum is empty. Thirst is best met by the guarded use of ice, the frequent moistening of the patient's lips, or the injection of sterilised water into the connective tissue of the axillæ. Large liquid enemata sometimes relieve thirst markedly, but the objections to these have already been given. When it is clear from the failing pulse, the falling temperature, the cold extremities, the dry tongue, and most fetid breath that trusting to nutrient enemata is not sufficient, limited quantities of champagne, brandy and soda-water, or some kind of meat-juice must be given by the mouth.

4. *Enemata*.—In intussusception and fæcal impaction, and in cases of stricture with a fæcal block above, large enemata may be valuable; but with these exceptions, and especially in all acute cases of obstruction, they are very rarely useful.

5. *Local applications*.—Material relief is often given by the assiduous use of quite hot flannel, wrung out of a 2 per cent. creolin-solution. This, which soothes with its heat and helps to sterilise the skin before operation, should be regularly renewed. Poultices are too heavy, and quickly get cold. Turpentine is sometimes applied on hot flannels. It has the objections of frequently slightly blistering the skin, thus rendering it tender for examination, and perhaps interfering later on with the incision of an operation. In a few cases the patient experiences greater relief from local cold, as by cracked ice applied at frequent intervals between two layers of flannel tacked together with a few stitches.

6. *Electricity*.—This is occasionally of service in fæcal impaction.

7. *Washing out the stomach*.—This step, recommended by Kussmaul, gives much relief in some cases where the stomach is distended with fluid. Where, however, fluids have been properly restricted from the first, it will not be required.

B. OPERATIVE TREATMENT.

Surgical Operations.—These include—(1) *Abdominal section*; (2) *Formation of an artificial anus*; (3) *Puncture*. Colotomy will be referred to under the treatment of chronic obstruction.

1. *Abdominal Section*.—A few most important points, many of them fallacies still unrecognised, first call for attention: (1) Acute and chronic obstructions do not always fall into distinct groups. (2) Chronic obstruction often puts on an acute appearance. (3) The demand frequently put forward at the present day that cases of acute intestinal obstruction require surgical treatment is a fair one, but for the reasons given above it is a mistake to expect a very large proportion of successes, even after early operations for intestinal obstruction. (4) Many leading surgeons have held strongly that the chief cause of the great mortality after operations for intestinal obstruction has been in their having been put off too long. While this is no doubt a chief cause, it is not the only one. It is a mistake to group all cases of acute intestinal obstruction together as all equally suitable for operation. *Post-mortem* evidence shows that a distinct proportion are from the first hopeless of relief by opera-

tion, others becoming hopeless so early in the case as to render any operation probably futile. Thus, with regard to operative treatment, cases of acute intestinal obstruction may be divided into these three groups: (a) *Cases probably hopeless from the first*—e.g. some cases of severe volvulus of sigmoid and colon; some cases of acute intussusception in infants; and cases of complicated snaring or matting, as in peritonitis started about the female pelvic organs, or in inflammation around mesenteric glands. (b) *Cases in which there is hope of doing good by operation*—e.g. cases of band, especially the single band in young subjects; some cases of intussusception, and of internal hernia. The question of benefit from operation in acute obstruction is intimately bound up with these two points: (1) the impossibility of making an accurate diagnosis of the nature or the site of the obstruction in many cases; and (2) the peculiar structure of the parts; thus, the intimate association of the intestine with the nervous system, the weakness and easy paralysis of its propelling power, and the readiness with which it is strangled, &c. Finally, among the conditions which handicap the explorer are (a) the tightness with which his hand is gripped by the abdominal wall here, not stretched as by a large ovarian tumour; (b) the way in which distended coils of intestine crowd up and get in the way; (c) the risk of fatally disturbing parts already known to be damaged; (d) the condition of the patient. A skilled surgeon should be called in as early as possible, as it is only fair that he should see the case early and throughout. When an operation is decided upon, the surgeon will be in a far better position than when called in, as too often happens, late in the case. When an operation is to be performed, the pulse should be fair, the temperature not falling, the abdomen not much distended, and with sufficient peristalsis to make it probable that there is little or no peritonitis. On the other hand, the operation should not be performed, as it too often is, on the merest chance of relief, when the abdomen is enormously tympanic, when the temperature and pulse are falling, and the patient passing into irrecoverable collapse.

The Operation.—Only the chief points can be noted here. The bladder being emptied, and the abdominal wall sterilised, the patient, with his extremities warmly clad, is placed on a water-bed filled with hot water. Everything that can possibly come within the field of operation must be scrupulously cleansed before the operation, and kept aseptic. An anæsthetic having been given, the abdomen is quickly opened along the linea alba below the umbilicus; and all hæmorrhage being arrested, two or three fingers are introduced, and the following possible sites of strangulation first looked to: (1) the cæcum, its condition of distension or emptiness telling whether the obstruction is below or above it. (2) The inner aspects of the femoral, inguinal, and obturator apertures, to make sure that no tiny hernia exists, imperceptible from the outside. (3) The brim of the pelvis, as bands of omentum are often fixed hereabouts, and also because, in women, local peritonitis, originating in the uterus or its appendages, is not infrequently the source of the obstruction. If the above search with two or three fingers or the whole hand fails, and it often will when distension is present, embarrassing the fingers in their movements and obscuring the relation of parts, one or two loops

which lie nearest the wound should be scrutinised and followed in the direction of increasing congestion and distension, thus leading to the obstruction. If this prove fruitless, the most distended portion of the intestine must be drawn out (under cover of sterilised towels) bit by bit from the upper part of the wound and passed in again, after examination, into the lower angle, in such a way that at no time are more than five or six inches of intestine exposed. After drawing out and replacing some feet of intestine in this way, it is probable that, owing to the increasing congestion or resistance, the surgeon will reach the obstruction. An assistant should hold the coil from which the surgeon starts under a hot sponge, to prevent the same ground being traversed a second time. If after five to ten minutes' search the mischief is not found, the surgeon must decide between making an artificial anus and closing the wound, and enlarging the latter and allowing all the coils to prolapse under hot sterilised towels, frequently renewed. The decision must turn on the condition of the patient and the surroundings of the surgeon. On the one hand it is only taking this bold step which will, in a large number of cases, bring to light the cause of the obstruction. On the other, if the coils be distended, it will be impossible to get them back without draining them and closing the opening. The needful manipulations necessarily produce much shock, and perhaps inflict serious damage. When the obstruction is found, it must be dealt with according to its nature. Thus an opening (as in the mesentery) must be stretched with the finger-nail and the bowel withdrawn; omental bands, if not torn through, divided between two chromic-gut ligatures; any diverticular band brought up into view, and divided with similar precautions, or, if the patient's condition admits of it, resected and the cut ends cleansed and closed. Resection of gangrenous intestine, and intestinal anastomosis, may have to be resorted to. The best modes of dealing with volvulus, intussusception, and gall-stone, are given under their respective headings. It remains to allude very briefly to two most important steps, the omission of which, owing to the hurry at the close of an operation for intestinal obstruction, often renders what has been done futile. The first is that it is absolutely useless to leave the abdomen full of distended intestine. This will inevitably prove fatal, partly by intestinal toxæmia, partly by pressure on the diaphragm, and cardiac collapse. Its removal is imperatively needed, either by making an opening in the intestine, draining this and then closing the opening, or by the formation of an artificial anus. The other step is the thorough cleansing of the peritoneal sac when this has been contaminated, either by sponges or by flushing with a hot solution of boiled water, introduced using an irrigating tube. In these cases a Keith's tube should be introduced into the pelvis and sucked out regularly.

2. Formation of an Artificial Anus; Enterotomy.

This is done under the following conditions: When the patient's condition does not admit of any searching for the cause of the trouble, when the operator cannot detect the site of obstruction, or finds that he can neither deal with this nor perform resection, or intestinal anastomosis. The artificial anus is best made by tying in a Paul's tube by means of a purse-string suture. The coil should first be brought well outside the abdomen, and emptied with gentle pressure before the suture is inserted. Another

means, when a Paul's tube is not forthcoming, is to bring out a coil, fix it by sutures, and then open it by a trocar and cannula passed through sterilised thin indiarubber sheeting, so that liquid fæces do not flood the wound, &c. Nélaton's operation is usually adopted. Making an artificial anus is merely palliative; and should only be resorted to when other steps fail or are impracticable, and when it is certain that the obstruction is low down in the small intestine. The chief drawback to this method lies in the extreme annoyance the patient suffers afterwards from the continual escape of liquid fæces, and the certainty of marasmus if the opening in the intestine be high up.

3. *Puncture of a Distended Coil by Trocar and Cannula.*—This step should be abandoned. While in a very few cases puncture has apparently proved efficient, there is no doubt whatever that the number of cases in which this method has been fruitlessly employed, and which have never been published, is infinitely greater. The chief risks are: (a) Not hitting the right coil; thus one (though distended) may be hit so far from the obstruction as to give no real relief. In not a few the bowel below the obstruction may be punctured (Treves). (b) The puncture may give rise to no real relief, but to increased distress. (c) The puncture may be followed by fatal leakage into the peritoneal sac.

VARIETIES.—1. *Strangulation by Bands or in Apertures.*—As some at least of these depend upon the results of previous inflammation, it is important to inquire minutely into the early history.

ANATOMICAL CHARACTERS.—The bands causing strangulation may be adhesions resulting from peritonitis (omental), a persistent Meckel's diverticulum, or some normal structure abnormally attached. In any case it is the small intestine, and usually the end of the ileum, which is specially liable to become thus strangulated. A band or bands, sometimes rounded, sometimes flattened, may stretch from one part of the mesentery or omentum to another, or, oftener, may be attached by one end to the omentum or mesentery, and by the other to the bowel (only exceptionally to the large intestine), or to the abdominal wall or pelvis. Much more rarely are they found passing from one part of the bowel to another. The broader adhesions sometimes present slits in which portions of bowel may be caught. Similarly, ruptures or slits may occur in the omentum or mesentery, or even in very rare instances in the suspensory ligament of the liver, or broad ligament of the uterus. The lower attachments of the omental bands are usually to the parietes or viscera, to the brim of the pelvis, or to near the inner orifice of one of the rings. Of the diverticular bands, the most important is the one called 'true,' which is due to a persistent or partially obliterated vitelline duct. This band is single, and is attached at one end to the ileum from one to three feet from its termination; its other end may be free or attached in the vicinity of the umbilicus. Its structure may be like the intestine, or cord-like. The intestine may be strangled beneath it, when the band is adherent at both extremities, or snared and knotted up by it, in a much more complicated way, when its distal end is free. Other congenital bands may arise from the omphalo-mesenteric vessels. Strangulation may, much more rarely, take place in various forms of internal hernia (hernia into the foramen of Winslow, or into peritoneal pouches, mesocolic, duodeno-jejunal, or retro-peritoneal).

SYMPTOMS.—These are similar to those already described under Acute Obstruction. Strangulation of the small intestine by the above-mentioned bands or apertures is most commonly met with in early adult life, the average age being from twenty to forty. One sex does not appear more liable than the other, except in the case of strangulation by diverticula, which has been observed about twice as often in the male as in the female subject. The more youthful the patient, the more will a true diverticulum suggest itself. But strangulation is not unknown in much older patients, as shown by the subjects of herniæ and omental bands.

TREATMENT.—The surgeon may resort to abdominal section with much hope. As to the date of interference, the earlier the better, before the patient's strength is lowered by vomiting, and the operation rendered additionally difficult by distension.

II. *Volvulus.*—The pathology of this has been already given (p. 774).

SYMPTOMS.—In addition to the usual symptoms of Acute Obstruction, there are certain special points which may aid in the diagnosis. The patients are usually adults; and constipation has most likely been of long standing and habitual. The occurrence in insane patients, though the insanity probably only points to neglected bowels, has been sufficiently frequent to be noteworthy. The symptoms are urgent (with the exception, perhaps, of vomiting, which may be less marked than in other forms of acute obstruction), and may end rapidly in death. But the point which is likely to be distinctive of volvulus is the urgent distension of the abdomen, often due to one or more huge coils of large intestine.

TREATMENT.—Operative steps, taken early, give the only hope here; otherwise the huge distension, and the early stage at which inflammatory changes set in, rapidly bring about a fatal result. The distended sigmoid should be exposed and its contents evacuated by a trocar or aspirator passed through sterilised thin indiarubber sheeting so that liquid fæces do not contaminate the wound. If needful, the bowel must be incised and emptied, every care being taken not to infect the peritoneum. As soon as the distension is materially lessened, the twisted loop should be brought outside, the twist undone, the opening closed and the bowel replaced. If tympanites persist, the opening should be made into an artificial anus, or a right-sided colotomy performed, to relieve the cæcum. This has been done as a primary operation with complete success in a few cases. But owing to the rapidity with which gangrene attacks a volvulus, the treatment first given is much to be preferred.

III. *Intussusception or Invagination.*—This form of obstruction is most important, owing to its frequency in early life, its rapid fatality in many cases, and the number of brilliant successes which have followed insufflation and abdominal section.

ÆTIOLOGY.—Intussusception is the most common variety of obstruction to which children are liable, about one-fourth of the cases on record having occurred during the first year, and more than one half during the first seven years of life. In early life and childhood it is more frequent in males. Intussusception would appear to be brought about by some irregular peristaltic action of one part of the intestine, perhaps conjoined with inaction of another part. Sometimes it follows severe purging,

diarrhoea, or violent straining, sometimes the presence of worms, or a polypoid growth, especially in the lower ileum. In a few cases it has followed movements or strain, especially during the dandling and dancing of an infant upwards and downwards in the arms.

ANATOMICAL CHARACTERS.—In ordinary cases a transverse section will show three rings of bowel, and a longitudinal one three layers of bowel on each side. The external of these three layers is called the *intussusciens* or sheath, the middle the returning layer, and the innermost the entering layer, these last two, taken together, forming the *intussusceptum*. Of these layers, the outer and middle have mucous surfaces in mutual contact, and the middle and inner have serous coats thus opposed. The increase of the intussusception takes place by the entering and middle layers moving in together, and dragging in the outer one after them. Thus, while the inner bend between the entering and the middle layers remains the foremost part of the intussusception, the outer bend between the middle and outer layers is constantly changing. Between the middle and inner layers the mesentery or mesocolon or both, as the case may be, are drawn in. This fact determines, from the first, peculiarities in the shape of the intussusception; and, later on, the compression of the vessels brings about congestion, ecchymosis, swelling, and sloughing. Thus the traction on the mesentery, often considerable as the invagination increases, causes a curving of the cylinder of the intussusceptum, and to a less degree that of the sheath, towards the root of the mesentery. It also may pull the axis of the intussusceptum and its terminal orifice out of that of its sheath, and nearer the mesenteric border of the intestine, the orifice of the end of the intussusceptum becoming also, by the traction, slit-like. Intussusceptions occur much more frequently in some parts than in others. Thus, when the small intestine, especially the ileum and lower jejunum, is involved, it is spoken of as the *enteric* variety (30 per cent.). In the ileo-cæcal region two forms are found: (*a*) the *ileo-cæcal proper*, in which the ileum and cæcum, preceded by the valve which forms the most advanced point of the intussusceptum, pass into the colon. This variety forms 44 per cent.; it may attain great size, the valve reaching as far as the anus, and being then liable to be mistaken by careless observers for a prolapsus recti. (*b*) In the other, *ileo-colic* (8 per cent.), the lower part of the ileum is prolapsed through the ileo-cæcal valve. The *colic* variety (18 per cent.) may occur anywhere in the large intestine, but is most frequent in the descending colon and sigmoid flexure.

SYMPTOMS.—In *acute* intussusception the onset is sudden; pain is an early symptom, and of a colicky, gripping character, but not as a rule so agonising as that which may be produced by a band. Like tenderness, it may here be a guide to the site of the intussusception. Vomiting is not so urgent as in strangulation by bands or other conditions. And the same is true of constipation: this is rarely absolute; usually it is replaced by a diarrhoea, at first fecal, then fecal mingled with blood-stained mucus, the admixture of fecal matter becoming less or ultimately absent altogether. Severe tenesmus and straining recur at frequent intervals: and these, with the absence of sleep, and the inability to take food, soon exhaust the strength of the little patients. On examination of the abdomen, the intussusception-

mass can be distinctly felt as a firm, cylindrical, sausage-like swelling, in all cases of ileo-cæcal intussusception. In these cases it may traverse the right flank, the upper part of the abdomen, the left flank, and even be felt *per anum*, or seen projecting. With the above symptoms are present, to a varying degree, those of shock and peritonitis.

Under the name of *chronic intussusception* are included those cases of intussusception which have a duration of one or more months. These are rare, but their extreme importance is shown in the words of Treves—that no form of intestinal obstruction offers so many difficulties in the way of its recognition, and no form has been the subject of more error in diagnosis. This form appears most frequently in adult males. Its course is most irregular. The onset is sudden only in about one-third of the cases—a point, when present, of much value in the diagnosis of this from other forms of chronic obstruction. Pain, seldom severe, may be entirely absent for long intervals, these becoming shorter as the disease advances. Vomiting is only marked in about half the cases; it is feculent only in about 7 per cent. The action of the bowels varies greatly. As a rule they are irregular, more often with a tendency to diarrhoea than towards constipation. In about 50 per cent. a bloody discharge from the anus occurs. Distension of the abdomen is slight, and may be absent save during attacks of temporary obstruction. A tumour is to be felt in about half the cases. The general condition is one of wasting and anæmia, the patient not infrequently dying of marasmus.

COURSE AND PROGRESS.—(1) *Acute*. Unless relief is obtained, the case will end fatally from shock and exhaustion within three to five days in young children, or in infants in a much shorter time, or within a week or ten days in older children; in adults between the second and third week. These cases lead up to the second class of *subacute* cases, in which life may be prolonged for three or four weeks. (2) The case may be more or less *chronic*, and terminate in death only after a period of several weeks or months, from wasting and exhaustion or peritonitis and enteritis, with or without perforation. Lastly, recovery may take place after sloughing, separation, and evacuation of the invaginated bowel. This last event, of great interest, but by no means necessarily curative, is extremely rare in children under two. It has occurred proportionately in 20 per cent. of ileo-cæcal, in 28 per cent. of colic, and in 6 per cent. of enteric cases. Its most frequent period of occurrence is from the eleventh day to the period between the third and fourth week (Leichtenstein). Briefly stated, it is brought about by adhesions forming between the invaginated and receiving portions of the bowel, and death of the intussusceptum from strangulation of its blood-supply. In most of the recorded cases it has been some portion of the small intestine that has come away; in some the cæcum and its appendix with portions of the colon. Sometimes the sloughed intestine is evacuated in shreds, at other times in its entirety. While this result is usually met with in acute cases, it may occur in chronic ones that end acutely. The signs are great fetor of the stools, and gangrenous shreds of intestine found in them. It has been already said that this process can by no means be relied on to save life. The giving way of the adhesions, and fecal extravasation, chronic diarrhoea, hemorrhage,

pyæmia, and, later on, a stricture, may prove fatal.

TREATMENT.—Acute intussusception, especially in the child or infant, demands prompt and active measures. Opium and belladonna should be given at once and sufficiently to check undue peristaltic action and relieve pain. The abdomen should be kept covered with hot fomentations; and the amount of nourishment given by the mouth should be most strictly limited. In young children especially, owing to the rapidity with which their strength runs down, and in all cases, so as to ensure a condition which still admits of replacement, reduction should be attempted as early as possible. Inflation should be preferred to injection as somewhat less risky. The child being placed fully under an anæsthetic, and its pelvis and lower limbs somewhat raised, the nozzle of a Lund's inflator, a rectal enema-tube, or a full-sized catheter well smeared with vaseline, attached by tubing to a bellows, is carefully passed into the bowel. The nates being securely pressed around the tube, air is steadily pumped into the colon, while the surgeon keeps one hand on the abdomen, not only to prevent over-distension, but also to watch for any receding of the tumour towards the cæcal region. With regard to the amount of force used, replacement of the bowel can usually be effected only by considerable distension of the whole colon, and this requires a good deal of rather forcible pumping to complete it. This is especially the case with regard to the last few amounts of air sent in (Goodhart). Inflation failing, if the condition of the patient admit of it, more powerful means may be made use of by connecting the rectal tube with an irrigator placed not higher than three feet above the bed, a more equable and forcible distension being thus obtained (Goodhart). Goodhart points out that the last method entails a greater risk of rupture of the bowel, but that the end justifies the means, considering the great danger of these cases. If the above methods fail, abdominal section should at once be resorted to in suitable cases. The following points are here important: (a) *The age.* In infants under a year, unless reduction is early tried and quickly successful, the prognosis is very grave. Even at this early age there is an increasing tendency on the part of hospital surgeons to resort to operation early. It is felt that too much importance has been attached to the cases published in which inflation has met with success; that these cases in reality bear a very small proportion to those which have been treated in the same way unsuccessfully. Again, it is felt, and rightly, that valuable time is often wasted in repeated attempts at inflation often unsuccessful in reducing the intussusception completely. Finally, the increasing amount of success which attends operative interference shows that, though the vitality of these little patients is small, intussusception is favourable for operation, in that it is one of the very few forms of acute intestinal obstruction in which the condition can be accurately diagnosed, its site definitely located, and the amount of manipulation and interference is therefore brief and slight when the surgeon is asked to operate early. (b) *The condition of the patient as to collapse, &c.* (c) *The duration of the case.* In the majority, especially in children, the tendency of the condition is to strangulation and not simply incarceration, and while the rapidity of the strangulation varies a good deal, the chances of inflation or injection are small, unless in

recent cases. (d) It is thus of the utmost importance to decide *whether the bowel is strangulated or incarcerated.* Hutchinson points out that the severity of the symptoms will be helpful here, namely, the urgency of the vomiting, the degree of the constipation, the character of any stools passed, and, above all, as utterly incompatible with gangrene, advance of the tumour onwards.

Only the chief points in the operation can be given here. The peritoneal cavity being opened by a median incision with the umbilicus for its centre, the intussusception is found. For a few minutes careful pressure should be made on this to diminish the oedema and inflammatory swelling, before any attempts at reduction are made (Senn). The wound being sufficiently enlarged so as to admit of two fingers of each hand, and the small intestine packed away, if the mass cannot be hooked up into the wound it must be reduced *in situ*. This can be done, if there are no adhesions, either by traction upwards on the upper part of the invagination; or, as thought better by Hutchinson, by finding the lower part, holding the ensheathing part so that it cannot be drawn into constricting folds, and pressing out the contained bowel by gentle squeezing movements between the finger and thumb. These movements must be continued, and the finger and thumb gradually shifted upwards along the gut till every atom of the mass is reduced; this being often made known by the appearance of the vermiform appendix. Every care must be adopted to finish the operation as speedily as possible, and every precaution taken against shock. The chief points in the after-treatment are the application of warmth, and the administration of milk, brandy, and laudanum. If reduction be found impracticable enterectomy is permissible.

IV. Impaction of Gall-stones.—Gall-stones large enough to block the gut may enter the intestine after a process of inflammatory adhesion and ulceration between the gall-bladder and the duodenum or colon. In such cases, though there is usually a previous history of more or less suffering in the hypochondriac region (which may assist in the diagnosis), those paroxysms of pain and the jaundice which accompany the passage of gall-stones down the duct may not have been experienced. Obstruction from this cause is comparatively rare. It is met with far more frequently in the female than in the male, and with very few exceptions after late middle life. The patients are very often obese. As a rule the obstructing gall-stone is single. The most common seat of impaction is the lower ileum, and next to this the jejunum.

SYMPTOMS.—These are usually sudden and acute; death from enteritis conjoined with those of acute obstruction occurring, as a rule, in about five days, perhaps earlier, as the result of shock. Recovery rarely takes place.

DIAGNOSIS.—This is aided by the sex, age, and previous history of the patient; the acuteness of the symptoms; and perhaps by the recognition of a more or less distinct hard lump corresponding to the obstructing gall-stone.

TREATMENT.—If a very short trial of palliative treatment is futile, abdominal section is here the patient's only chance; though, owing to the usual age, habits, and condition of the tissues, the step must always be a very anxious one. The stone having been found, it may be dealt with—(1) By trying to pass it on into the large bowel. (2) By

intra-intestinal crushing, either between the fingers or by flat-bladed forceps guarded with indiarubber tube. (3) This may be facilitated by Tait's suggestion of puncturing the stone with a needle, passed obliquely. (4) The loop being drawn outside, the stone may be extracted and the opening most carefully closed. If the bowel immediately around the calculus be inflamed, the stone should be pushed into a healthy portion before extraction.

V. Contractions.—In this class may be included cases due to adhesions, kinking or compressing the gut, or matting together several coils; and those where mischief, inflammatory or malignant, has closed the lumen by traction, or narrowed it—as when the mesentery puckers from old tubercular or malignant mischief. These cases are among the gravest and the most hopeless of intestinal obstructions; they affect the small more frequently than the large intestine; and are often preceded by old peritonitis.

SYMPTOMS.—Owing to the rarity of stricture of the small intestine, this group practically comprises all cases of chronic obstruction of that part of the bowel (Fagge). The attacks are often repeated, and the final one is in reality acute supervening on previous chronic mischief. Vomiting and constipation will for a long time be irregular and uncertain. Visible peristalsis, and colicky attacks of pain with loud rumblings, will probably be marked features.

TREATMENT.—For some time this must be palliative with a view of preventing obstruction. Abdominal section is here especially likely to be disappointing, owing to the complicated nature of the obstructing agency, the fact that there may be more than one seat of obstruction, and the intimacy with which one or more coils of intestine are matted to each other or to adjacent viscera. Formation of an artificial anus (*vide supra*), and still more colotomy where the large intestine is affected, may give relief. When the opening is made in the small intestine, it must be low down, or miasmus will follow.

VI. Obstruction from Stricture.—(a) *Simple cicatricial stenoses.* These may result from the effects of dysenteric, tubercular, or syphilitic ulceration of considerable extent. The dysenteric are most frequent in the lower part of the large intestine, the tubercular in the lower ileum and about the ileo-cæcal valve, and the syphilitic in the rectum. Rarer instances of stenosis occur after injury, the sloughing off of an intussusception, the strangulation of hernia, or the ulceration produced by temporarily impacted gall-stones, fecal masses, or foreign bodies.

(b) *New-growths.*—A more exact pathology has practically narrowed down these to one kind, namely, cylindrical epithelioma. Very rarely innocent growths—e.g. fibromata or adenomata—may cause more or less obstruction, usually by becoming polypoid. The locality attacked is in the very great majority of cases on the left side. Cases occur in about equal proportions in the rectum and sigmoid flexure: then about half as frequently in the left colon and splenic flexure; the remainder being met with in the ascending colon and hepatic flexure.

SYMPTOMS.—In the earlier stages these are often by no means marked. Disordered, irregular, and unsatisfactory action of the bowels, and general discomfort, with intervals of comparative ease, constitute the earliest indications. At this time, owing to the forgetting or deferring of an examination, the cases are far too frequently treated as instances of flatulence, indigestion, and constipation. Later on,

the symptoms of obstruction become more pronounced. In most cases abdominal distension, accompanied by fetid eructations and pain, comes on, varying in degree from time to time. The pain is usually distinguished by its paroxysmal character, and its relation to unwise feeding. Nausea is an early symptom; but vomiting usually appears late, and usually only becomes feculent in the final attack of obstruction. The motions are always unsatisfactory, the bowels not acting without aperients, loose stools often alternating with scybala, or broken-up bits with slime and mucus coming away. Troublesome, teasing tenesmus, causing the patient repeatedly to seek relief from the sensations of an imperfectly emptied bowel, is often present when the stricture is low down. Peristaltic movements of the intestines, accompanied by colicky pain and rumbling borborygmi, become increasingly frequent and manifest as the muscular coat hypertrophies. As the case progresses, the general condition of the patient, the increasing emaciation and cachexia, and the failure of treatment, all point to the malignant nature of the case.

COURSE AND TERMINATIONS.—The course of all such cases, though very variable in duration, is progressively unfavourable, and sooner or later death supervenes, usually from peritonitis, with or without perforation, or from exhaustion by prolonged suffering and possibly suppuration. Absolute occlusion, as a rule, comes about slowly. In some cases it is never completely established; in others, it occurs suddenly, from impaction of hardened feces or undigested food. It is worthy of note that, even in cases in which the seat of constriction is in the sigmoid flexure or rectum, the greatest evidence of stress due to the fecal accumulation, distension, ulceration, and perforation, is often found in the cæcum.

TREATMENT.—From the very first, as soon as there is reason to suspect the presence of a stricture, the most careful attention to diet, and the regular administration of such medicines as will favour soft semi-solid motions, should be insisted on. In other words, if the misery of death by obstruction is to be warded off the patients must pay the strictest attention to their in-take and their out-put. If these points are attended to, the patients may be kept, for the year or two which the disease takes to run its course, in comparative ease; but it is extraordinary how frequently and at what cost these most obvious precautions are still neglected. Patients, the subjects of stricture, should be warned that they are living on the brink of a precipice. As a rule, carelessness in diet brings its own penalty, and most patients willingly acknowledge the relief which such a dietary as the following gives:—soups; milk, bread and milk, milk and oatmeal, arrowroot; poached or whipped-up eggs, a few oysters, a little vegetable (especially those which leave a small residue), breadcrumbs, yolks of eggs, with plenty of gravy, or well puréed with milk; a little underdone meat, well pounded or shredded. In the early stages, and later on in the intervals of relief from threatening obstruction, aperients should be given regularly. There is nothing better than an ounce of castor-oil twice a week, and some laxative daily, such as cascara sagrada tablets, compound liquorice powder, a pill containing aloes, compound extract of colocynth and oil of juniper—one of these may be administered overnight, or Hunyadi János, or a similar water, is given in the morning. Where

obstruction is actually threatening, a laxative such as castor oil or sulphate of magnesium may, if retained, still give great relief if combined with a little tincture of opium, and aided by enemata of castor oil. But where obstruction is actually present, the case must be treated on the usual lines, a sedative here replacing laxative treatment.

When the above treatment has failed, or when the case is seen too late and obstruction is present, lumbar colotomy (on the right or left side, according to the indications afforded) is, on the whole, the safest operation, and should not be too long deferred. Where there is not much distension, and the operator has skilled assistance, it will be better to open the abdomen in the middle line, locate the growth, bring this outside, and fix it over a glass rod or a bougie, and open the bowel by tying in a Paul's tube (*vide supra*). Later on the growth may in favourable cases be removed.

VII. Obstruction from Compression from without.—Various viscera, enlarged and displaced, especially the uterus and ovaries, and in rarer instances the spleen, the kidney, or even a distended bladder; tuberculous or cancerous glands, tumours of the omentum, growths from one or other part of the abdominal or pelvic parietes, hydatid cysts, &c., may so compress a neighbouring portion of bowel as to lead to obstruction.

DIAGNOSIS.—Careful examination, including that *per vaginam* and *per anum*, together with the history of the case, consideration of the collateral signs and symptoms, and in some cases, as where the swelling is cystic, an exploratory tapping or aspiration, will generally suffice to establish, approximately at any rate, the existence of this form of obstruction.

TREATMENT.—This consists, firstly, in the removal of the cause, if practicable; secondly, where this is impossible, in relieving the obstruction. By altering the position of the body, the displaced viscera may sometimes be moved so as no longer to compress the bowel; tumours—ovarian, uterine, renal, or hydatid—may be dealt with by operation. Where this is impossible, manipulation or copious enemata may be employed, or sedatives may be tried, in the hope that the bowel may, under their influence, release itself. But if none of these measures should be applicable or successful, and if the symptoms of obstruction be severe, resort to colotomy, or the making of an artificial anus by abdominal section, may become needful.

VIII. Obstruction from Impaction of Foreign Bodies, Intestinal Concretions (Enteroliths), &c.

(a) Foreign bodies in bulk, such as bones, coins, &c., occasionally find their way into the intestines. In a considerable proportion of cases they are evacuated *per anum* without much inconvenience; in some cases they give rise to enteritis and various other intestinal troubles; in some rare cases they lead to more or less complete occlusion, with acute or subacute symptoms.

(b) Foreign bodies, as hair, &c.; skins, seeds, and stones of fruit (the husks of cereals, and oats especially), the curds of milk in young children, and some medicinal substances, as magnesia, chalk, iron oxide, &c., taken over a long interval, may accumulate and give rise to more or less complete obstruction. Such masses constitute the large proportion of the so-called 'intestinal concretions' in the human subject.

(c) Hard concretions (enteroliths), consisting for the most part of phosphates of lime and magnesium, with organic material, and having usually as a nucleus some foreign body or hardened fæces, have rarely been met with.

Intestinal concretions are most frequently found in the cæcum or rectum; much more rarely in the ileum. They are slowly formed, and rarely bring about intestinal obstruction. *See* CONCRETIONS.

TREATMENT.—As a rule, purgatives can only do mischief. Sedatives, combined with laxatives, favour the gradual onward passage of the foreign body. If absolute impaction has clearly taken place, and the symptoms are urgent, abdominal section and extraction may be imperative.

IX. Obstruction from Impaction of Fæces. Prolonged constipation may lead to definite obstruction by impaction of fæcal masses, conjoined with paralysis and inaction of the bowel from distension, and contraction of the empty portion below. Sometimes the occlusion is rendered more absolute and irremediable by the doubling or dragging down of the bowel by the weight of its contents. The seat of the obstructing fæcal mass is usually the sigmoid flexure or the rectum; but great accumulation and its effects—distension, ulceration, perforation—are often most manifested in the cæcum. This cause of obstruction is most frequently met with in women of sedentary habits, after middle life, and especially among hypochondriacs or lunatics.

SYMPTOMS.—These are characterised by their chronicity; complete occlusion, as a rule, coming about slowly. There is little or no actual pain during the earlier stages; and even during the later stages, in the absence of complications, it rarely becomes acute. Vomiting is altogether absent at first; in the later stages there may be much nausea, accompanied with foul evacuations, and, towards the last, fæculent vomiting. Absolute constipation is slowly established, and then may last for two or three months. In a few cases the extraordinary periods of seven, eight, or even nine months have been reached without relief (Treves). Before the constipation has thus become absolute, it has very likely been interrupted by attacks of diarrhoea, due to catarrh of the intestine above the impaction, and giving very imperfect relief. The fæcal masses can sometimes be felt on examination of the abdomen, or they may be concealed by the presence of fat or flatulent distension.

COURSE.—In a considerable proportion of these cases relief may be afforded by appropriate treatment. In some, death ensues from gradual exhaustion, from peritonitis after ulceration and perforation, or from acute obstruction owing to the bowel becoming suddenly blocked or acutely kinked.

TREATMENT.—For this *see* CONSTIPATION.

In the extremest cases, while colotomy is to be looked on as the very last resort, the practitioner should avail himself of this rather than allow his patient to die of over-distension and ulceration of the intestine. When relief has been obtained, the greatest care as to diet and after-management is necessary, in order to prevent that recurrence of trouble to which the patient remains liable. *See* CONSTIPATION.

X. Obstruction from Congenital Malformation.—Constriction or occlusion of this kind is very rarely met with in the duodenum at or about

the entrance of the common bile-duct, or about the junction of the duodenum with the jejunum; and in some cases has appeared to depend upon valve-like folds of mucous membrane, resembling enlarged or confluent valvulæ conniventes. The lower portion of the ileum, near the ileo-cæcal valve, or about the junction with the omphalo-mesenteric duct, appears most likely to be so affected. The colon (and almost exclusively the sigmoid flexure) is the part of the bowel most frequently constricted by the effects of foetal peritonitis, but instances are very rare.

All such cases are of pathological interest rather than of practical importance. Vomiting of meconium, absence of proper evacuation, straining, convulsions, and evidence of more or less severe suffering, are followed by speedy death, though in some rare instances life has been prolonged for weeks or even months. No treatment can avail, and surgical operations can only hasten death, or at best succeed in prolonging misery.

Very much more common, and somewhat more hopeful, are those cases in which there is congenital defect of the lower part of the rectum or anus, or both. They may be divided into—(a) imperforate anus; (b) anus in the natural position, but the rectum deficient.

TREATMENT.—Immediate relief may often be afforded by surgical operations, and in some instances more or less permanent good results have been obtained, and by persevering management maintained; but survival to adolescence or adult age has seldom ensued. See RECTUM, Diseases of.

INTESTINAL WORMS.—See ENTOZOA.

INTESTINES, Diseases of.—SYNON.: Fr. *Maladies de l'Intestine*; Ger. *Krankheiten des Darmes*.

The various morbid states exhibited by the intestines are attributable to (1) the effect of irritants introduced into the alimentary canal or developed therein in the course of perverted digestive action; (2) the invasion of parasites, microbic and other; (3) the influence of an unsuitable environment such as extremes of heat or cold; (4) functional disturbances of other systems, nervous, circulatory or excretory, or the conditions of general malnutrition which may be thereby brought about; or (5) lastly, to circumstances not as yet recognised. The influence of age and sex in the production of intestinal disease is largely determined by the extent to which these factors favour the incidence of the foregoing conditions. See PAIN in VISCERAL DISEASE.

The several diseased conditions of the intestines will be discussed in the following alphabetical order:—(1) Abscess in Walls; (2) Actinomycosis; (3) Amyloid Disease; (4) Anthrax; (5) Atony; (6) Atrophy; (7) Casts of; (8) Catarrh; (9) Concretions in; (10) Congestion; (11) Contraction; (12) Dilatation; (13) Gangrene; (14) Hæmorrhage from; (15) Hypertrophy; (16) Inflammation; (17) Malformations and Malpositions; (18) Neuroses; (19) New-Growths; (20) Paralysis; (21) Parasites; (22) Perforation and Rupture; (23) Spasm; (24) Syphilitic Disease; (25) Tubercular Disease; (26) Ulceration; (27) Vascular Changes.

1. Intestines, Abscess in Walls of.—See Inflammation of, p. 790.

2. Intestines, Actinomycosis of.—See ACTINOMYCOSIS.

3. Intestines, Amyloid Disease of. ANATOMICAL CHARACTERS.—See AMYLOID DISEASE.

SYMPTOMS.—The most prominent symptoms which this condition gives rise to, so far as the alimentary canal is concerned, are diarrhœa and hæmorrhage. Since the other important viscera are always simultaneously affected, other symptoms co-exist. The diarrhœa is rather characterised by fluidity than undue frequency of the stools, though the latter does occur; the evacuations often contain altered blood. It is rare to find either pain or tenderness; and the diarrhœa when once established rarely ceases. Hæmorrhage from the surface of the mucous membrane, independently of any ulceration, may occur from rupture of the diseased vessels.

TREATMENT.—Enemata of starch and opium are useful, though their effect is but temporary. Recovery, even from an advanced state, may follow if the cause, such as a suppurating joint, can be completely removed.

4. Intestines, Anthrax of.—See PUSTULE, Malignant.

5. Intestines, Atony of.—See NEUROSES of, p. 796.

6. Intestines, Atrophy of.—A general atrophy of the intestines accompanies a wasting of the entire body from any serious cause of malnutrition, such as starvation, where these organs are estimated in fatal cases to lose 42 per cent. of their weight, becoming extremely thin and transparent.

Intestinal catarrh may lead to atrophy of the bowels, even to an extreme degree. It may follow on a catarrh which is acute—this being frequent in children—or on the subacute or chronic forms. Certain parts of the canal are more liable to be affected than others, the cæcum, ascending colon, and lower end of ileum being the regions most commonly attacked. The change is almost restricted to the mucosa, the villi of the small intestine especially suffering, the thickness of the coat being reduced to one-fifth the normal in extreme cases, together with complete disappearance of Lieberkuhn's glands. The entire layer is replaced by connective tissue containing a few round cells, and presents a smooth appearance, with irregular thickenings at places; there is none of the pigmentation so constantly seen in the fibroid change of chronic catarrh; the muscular tissue, even of the mucosa, and the lymphoid follicles are unaffected. Nothnagel has also described areas of the muscular coat congenitally atrophied.

The symptoms referable to this condition, when the small intestine is involved, are those of general malnutrition from deficient absorption of the digested foods, and this may be so severe as to prove fatal, especially in infants and children. When the change is limited to the colon, there may be nothing beyond a slight diarrhœa, with bulky pulaceous offensive stools free from mucus. No treatment is specially available for this condition.

7. Intestines, Casts of.—See CASTS, p. 254.

8. Intestines, Catarrh of.—See p. 790.

9. Intestines, Concretions in.—SYNON.: Enteroliths; Bæzoars.—These are commonly met

with in the colon, cæcum, and appendix, which offer greater facilities of lodgment, and are liable to cause enteritis, ulceration, and perforation, or varying degrees of obstruction. See CONCRETIONS; STOOLS; and INTESTINAL OBSTRUCTION, p. 774.

10. Intestines, Congestion of.—See p. 804.

11. Intestines, Contraction of.—The calibre of the intestinal canal may be diminished by the pressure of tumours; by structural changes in the walls, such as cicatrices; or by displacements of portions of the bowel in invagination, &c. Such causes of stricture are more properly described under intestinal obstruction. See INTESTINAL OBSTRUCTION.

The term 'contraction' may be applied to that state of shrinking which the gut is liable to present below the seat of any permanent stricture.

Congenital malformations, producing contraction of the canal, even to complete occlusion, may be met with.

12. Intestines, Dilatation of.—The normal diameter of the small intestine may be taken as $1\frac{1}{2}$ inch throughout; and that of the large intestine as gradually diminishing from $2\frac{1}{2}$ inches at the cæcum to $1\frac{1}{2}$ inch at the upper part of the rectum. But the canal is evidently capable of distension much beyond these limits, as may be recognised when large accumulations of flatus or fæces occur. Such conditions, however, may disappear after death, the bowel returning to its proper capacity. These dilatations, therefore, may be regarded as temporary.

Other forms of distension of a more permanent nature are frequently observed.

Cases are sometimes met with in which extreme distension of the stomach, small intestine, and colon, either separately or together, occurs without any obvious cause, but perhaps associated with constipation. These have been provisionally termed *idiopathic*, and compared to similar affections of the œsophagus and stomach. The condition has been met with in children even at birth, or within the first three years of life, complicating diseases unconnected with the gastro-intestinal canal, such as broncho-pneumonia, or posterior basic meningitis, as well as in adults, and usually runs an acute and fatal course. In one case the colon was uniformly distended to a diameter of 6 to 8 inches; and in another the average diameter of the small intestine was twice the normal, the stomach also sharing in the distension; the person had been a large eater, and was extremely fat. The sigmoid flexure appears to be very prone to this distension.

In the greater number of cases the dilatation is attributable to the existence of some stricture in the course of the canal; and inasmuch as a persistent obstruction is usually located somewhere in the large intestine, it is the colon which most frequently suffers, and this may be so distended as practically to obliterate the ileo-cæcal valve. The mere accumulation and retention of the contents above the obstruction is doubtless one factor in causing the distension; but a diminished resisting power on the part of the gut probably co-exists, brought about by malnutrition of its textures. The muscular coat of the dilated portions is usually hypertrophied, while the mucous membrane is thinned and peculiarly liable to ulceration, the decomposing contents furnishing an exciting cause.

Localised bulgings or sacculations of the bowel may be met with, sometimes involving all the coats, and at others as diverticula formed by protrusions of the mucous membrane between the muscular fibres covered only by peritoneum. These 'false or distension-diverticula' are commonly found in old people suffering from chronic constipation or some condition causing general distension of the intestines; they are single or multiple, occasionally occurring in great numbers, and globular in shape; are most frequent in the colon, where they extend into the appendices epiploicæ, and occur less often in the small intestine along the mesenteric border. Inflammation from the irritation of fæcal or foreign matter is liable to be set up in them, leading to perforation into the peritoneum, or very rarely to communication with the bladder.

The existence of any extreme dilatation may be recognised by inspection or manipulation of the abdomen, especially if the parietes be thin and wasted, as they frequently are in such cases. Tympanites is present to a variable degree, uniformly distending the abdomen or causing asymmetrical swelling. Fæcal vomiting may occur in connection with the existence of a dilated intestine, but this is rather to be attributed to the primary obstructing cause, in the symptoms of which the few indications peculiar to this condition are merged. In extreme cases, the movements of the diaphragm may be interfered with, and the heart's action impaired even fatally.

Paralysis or atony from wasting or degeneration of the muscular coats, by diminishing the resistance of the bowel, allows of its distension. This is well exemplified in the extreme dilatation from flatus which so frequently accompanies acute peritonitis; and is comparable to certain cases of gastro-ectasis of a temporary character. See TYMPANITES.

13. Intestines, Gangrene of.

ÆTIOLOGY.—The immediate cause of the absolute death of a portion of the intestine is the complete arrest of the flow of blood through the part affected. This obstruction may be produced by:—

(i.) Embolism of the superior mesenteric artery. Several cases of this condition have been recorded.

(ii.) Thrombosis of the mesenteric veins. The perfect stasis induced by this cause is of very rare occurrence, but it has been seen to follow invasion of the portal vein by malignant disease, and associated with thrombosis of the femoral vein in the puerperal state.

(iii.) Detachment of the mesentery close to the intestine will be followed by gangrene of the part which is thus deprived of its blood-supply.

(iv.) Local constrictions of the bowel. This is by far the commonest class of causes of gangrene, and is the probable sequel of an unreduced strangulated hernia, an invagination (intussusception) or ileus. In these states the vessels are pressed upon, owing to the altered position of the gut, which, with the continuously increasing pressure of the œdema that follows the venous obstruction, leads to complete stasis.

(v.) The more gradual obstruction to the blood-flow, from constriction of the vessels by diseases of their walls, leads to sloughing, and tends to occur in amyloid disease of the intestines.

(vi.) Sloughing also occurs as a sequel of the long-continued pressure of hard fæces, or of the inflam-

matory state, when the process is of such intensity that complete cessation of the circulation takes place in localised spots, usually affecting the mucous membrane only, though occasionally penetrating deeper, ulcers remaining after separation of the sloughs. Owing to this cause is the frequently met gangrene of the vermiform appendix.

ANATOMICAL CHARACTERS.—From the nature of the intestinal tissues, the gangrene which is met with is of the moist variety. The portion of bowel which is affected is at first of an intense red colour, gradually increasing to purple, and even to black. The extreme congestion of the vessels leads to effusion of blood into the tissues, which are uniformly coloured; decomposition rapidly takes place in the stagnant blood, and the products acted on by the sulphuretted hydrogen of the intestines become black, all traces of red colour being soon lost. Meanwhile the mucous membrane and muscular coats are swollen and sodden by the serum and blood with which they are infiltrated; and a dark, black to ash-grey, soft, pulpy mass is finally thrown off from the healthy tissue. The extent of substance which may undergo this necrosis and be separated is extremely variable, from a mere slough of half an inch in diameter or smaller, to portions of bowel several feet in length.

SYMPTOMS.—The occurrence of symptoms whereby gangrene of the bowels can be diagnosed is scarcely to be expected. The signs for the most part resolve themselves into those of the cause, whether that be a plugging of the mesenteric vessels, or a localised enteritis. Extreme fetor of the stools may suggest its presence, but can afford no indication of the extent or depth of bowel involved, which are all-important data for prognosis, and to some degree for treatment. It is not until the sphacelus has been passed *per anum*, or until signs of ulceration are manifest, that the positive existence of gangrene can be ascertained. A very few hours suffice to produce this condition when once the cause is established; and since it cannot be either arrested or cured, the separation of the slough is to be desired, although fatal hæmorrhage or perforation may be associated with this process. Intestinal gangrene is always to be regarded as grave, though recovery not infrequently follows sloughing of considerable tracts when confined to the mucous membrane.

TREATMENT.—The circumstances associated with this morbid process as a rule preclude any treatment being specially directed towards it. If there be reason to believe that the entire thickness of the intestine is gangrenous, operative proceedings should be at once resorted to. Considerable success has followed resection of the dead part of the bowel, and union of the segments by sutures (*enterorrhaphy*).

14. Intestines, Hæmorrhage from.—An escape of blood from the intestines is a sign of certain morbid conditions rather than an actual disease itself; hence the cause of the hæmorrhage must be sought for.

ÆTIOLOGY.—The causes of intestinal hæmorrhage may be thus indicated:—

(a) *Increased blood-pressure*: Extreme congestion from such states as heart-disease, portal obstruction, embolism or thrombosis of the mesenteric vessels, intussusception, &c.

(b) *Affections of the intestinal walls*: Injuries of

the bowels; ulceration; vascular growths; hæmorrhoids; amyloid disease of the walls.

(γ) *Primary morbid blood-states or deterioration of vessels*: Purpura hæmorrhagica; hæmophilia; scurvy; leucocythæmia; yellow fever and severe intermittent and remittent fevers.

(δ) *Occasional causes*: Bleeding into the bowel from the stomach; rupture of an aneurysm into the intestine.

The mere enumeration of the causes must here suffice. It is obvious that the relative frequency of these conditions differs considerably, and in many cases the cause is at once apparent, while occasionally the source of the blood may be more obscure. It would seem from statistics that intestinal hæmorrhage is of more frequent occurrence in males, as gastric hæmorrhage is more common in women; the latter fact being explained by the greater liability of females to ulcer of the stomach, as the former appears to be by the preponderance of males suffering from the determining causes of hæmorrhage, such as liver-disease.

SYMPTOMS.—Associated with the symptoms special to the loss of blood, which are in the main similar to bleeding from any other organ, there are the signs and symptoms of the causal disease. The extent of the hæmorrhage will necessarily largely determine the symptoms, many bleedings being so trivial as to give rise to no appreciable effects, and in extreme cases the loss being so great and sudden as to lead to rapid collapse and death. Between these extremes all degrees of anæmia, faintness, pallor, giddiness, and failing pulse may be observed. A sensation as of a warm fluid flowing into the abdomen is occasionally complained of, but otherwise hæmorrhage in this situation is seldom possessed of characteristic features. Abdominal pain may accompany intestinal hæmorrhage, and is specially severe in embolism of the mesenteric arteries, but this symptom is not to be attributed to the bleeding, both being associated manifestations of a common cause. The occurrence of the above-mentioned indications in the course of a disease liable to lead to this condition would point to hæmorrhage, especially if there be a fall in temperature from a previous pyrexial state.

Occasionally the escape of blood is beneficial. This is particularly the case where the cause is a congestion of the intestinal tract, with or without hæmorrhoids. Thereby the fulness of the bowels is relieved, and a more equable circulation is established. In some cases of typhoid fever, contrary to what might be supposed, improvement has been noticed to follow a moderate loss of blood (Trousseau).

Except in such cases as when the effusion of blood is so excessive that death takes place before any escapes from the bowel, intestinal hæmorrhage reveals itself sooner or later in the character of the evacuations. If the cause be situated immediately within the anus, or the blood be sufficient in amount to escape alteration, then the red colour is retained. The hæmatin is readily affected by the sulphuretted hydrogen in the canal, and converted into a blackened material, sulphide of iron being formed, which stains the fæces; or a black tarry substance is evacuated, being the altered clotted blood (*see MELÆNA*). When the blood has undergone this change, the source of it is in the stomach or first part of the duodenum; blood from the colon—where it is usually due to ulceration—being passed adherent

to the fæces. The position of the source, the quantity, and the duration of its stay in the canal, largely determine the extent of alteration in the blood, and its degree of admixture with the fæces.

DIAGNOSIS.—The history of the case; the condition of the patient; and the character of the voided blood (*see* *MELÆNA*; and *STOOLS*) are the points upon which a diagnosis of the cause of intestinal hæmorrhage is to be based.

PROGNOSIS.—The amount of blood evacuated is not a sure guide to forming an opinion of the result. It is difficult to estimate the actual quantity lost, since much may be retained in the bowel. The general condition of the patient, especially the state of the pulse, is of far more importance; while allowance must be made for the nature of the cause, not forgetting the occasional favourable import of a flux.

TREATMENT.—In a certain number of cases bleeding from the bowel is uncontrollable; in others it is capable of cure; while in a third group it is rather to be encouraged. When arrest of the hæmorrhage is desired, rest, both general and local, is essential; the patient should be maintained in the recumbent position, as thereby the liability to syncope is averted; and the canal is to be kept quiet by abstinence from food, and the free use of opium, to prevent peristalsis.

The active treatment is to be directed to withdrawing the blood as much as possible from the affected region, by means of heat, sinapisms, dry-cupping, &c.; and to the application of styptics to the bleeding surface, or the administration of such remedies as arrest bleeding after their absorption into the blood. The most effective agents given by the mouth are turpentine in a full dose of 40 to 60 drops, followed by half-drachm doses every three hours; and the *Pilula Plumbi cum Opio* (B.P.) gr. v., every four or six hours. Tannic acid and the vegetable astringents are usually too slow in their action to be of much avail. Bitartrate of potassium in two-drachm doses is of much benefit in arresting the bleeding of piles; for which purpose also, as well as for vicarious hæmorrhage, or the flux of passive congestion from the lower bowel, the writer has found frequently repeated doses (m v. to m viii.) of tincture of hamamelis most efficacious. Probably the most reliable remedy is the *Injectio Ergotæ hypodermica* in five-minim doses, repeated if needful. Should the source of the hæmorrhage be within the range of local application by rectal injections, the most useful agents for this purpose are turpentine one to three drachms, with four to eight ounces of mucilage of starch; equal parts of tincture of perchloride of iron and water; or tincture of hamamelis, a drachm to three ounces of water, as an enema. Such astringents as tannic acid, opium, or hamamelin may be conveniently administered in the form of suppositories.

When the hæmorrhage is distinctly the result of engorged vessels, its occurrence should not be checked, provided it be not excessive. Sulphate of magnesium in full doses, with a few minims of diluted sulphuric acid, is then of great service.

The giving of stimulants is a procedure that involves careful judgment. While undoubtedly the tendency of loss of blood is to produce death by syncope, it is also true that faintness itself favours the cessation of the bleeding, and, so far as a general direction can be given, stimulants should be avoided, unless there be reason to fear, from the condition of the patient, character of the pulse, &c.,

that the syncope is grave. Short of that, alcohol, by temporarily increasing the heart's power, increases the bleeding.

Transfusion of blood or of 'normal saline' solution should be resorted to in extreme cases. *See* *SALINE SOLUTION*.

15. Intestines, Hypertrophy of.—This is always of local occurrence, a general hypertrophy, involving the entire length of the bowel, being practically unknown.

In chronic enteritis the mucous, submucous, and even muscular coats are apt to become much thickened, and though this is partly due to an excessive formation of connective tissue, there is also some actual hyperplasia of the normal structures.

In portions of the intestines above an obstruction, a true hypertrophy of the gut, particularly of the muscular layers, is to be found; and, as already said, this is usually associated with dilatation of the tube. Marked hypertrophy, especially of the longitudinal muscular bands of the colon, has been noticed in those cases of so-called idiopathic dilatation where no obvious obstruction exists. The pathogeny of this condition is obscure, for it does not appear probable that it precedes the dilatation, as in the heart, but rather that it is developed coincidentally.

It is rare for this condition to be other than inferred during life; it often gives rise to no symptoms and calls for no treatment; and when established is rather of the nature of a compensatory state. The congenital cases are, however, generally fatal, but relief is sometimes afforded by right-sided colotomy.

16. Intestines, Inflammation of.—*SYNON.*: Enteritis; Fr. *Entérite*; Ger. *Darmentzündung*.

Under this term are included all those structural changes in the mucous membrane of the intestinal tract which primarily follow the application of an abnormal irritant, provided that the irritant be not of sufficient intensity to produce absolute destruction of tissue. Such changes will involve more or less all the tissue-elements of the mucous membrane, and may extend to the muscular, or even the peritoneal coat. The inflammatory process may present considerable variety in type. The simplest form, to which the term 'catarrh' may be applied, passes, by almost insensible gradations, from the tissue-changes met with in the course of normal digestion, to a distinct condition of disease. To this there may be superadded certain specific characters due either to the nature of the cause, or to the predisposition of the tissue affected, or to both (*see* *INFLAMMATION*). There are thus differences in the severity with which enteritis may occur; but in all cases the essential characters of inflammation are present, which may be regarded as the results of the irritant *plus* the efforts at repair on the part of the affected tissue.

The morbid process may affect the intestine throughout the greater part of its length, either in common with or independently of the stomach—*general enteritis*; or it may be distinctly limited to certain parts of the canal—*local enteritis*, including duodenitis, typhlitis, colitis, and proctitis. As a rule, the term *enteritis* is restricted to inflammation of the small intestines, while *colitis* denotes a similar affection of the large bowel.

In respect to duration and intensity, enteritis may be *acute* or *chronic*.

(A) **Acute Enteritis.**—Acute enteritis is meant

to include all those cases where the essential features of an inflammation are present, varying in severity from a simple catarrh or muco-enteritis, to those graver forms possessed of special features, such as suppuration and ulceration. The more severe cases, especially in children, are sometimes called simple or English cholera, or *cholera infantum*.

ÆTIOLOGY.—*Predisposing causes.*—(a) Age especially predisposes to enteritis; for although it may occur at any period of life, infants and children during the period of dentition are peculiarly susceptible.

(b) The season of the year appears to exercise an influence, for during the summer and early autumn this disease is certainly much more frequent; and particularly so when there is extreme difference between day and night temperatures, or when the heat is associated with much drought.

(c) Occasionally this malady would appear to be epidemic.

(d) Certain mental and emotional states undoubtedly confer a liability to the occurrence of symptoms which are practically indistinguishable from those of a catarrhal enteritis.

(e) Conditions of general ill-health and marasmus, especially in children, predispose to intestinal catarrh.

Exciting causes.—1. Irritating ingesta of the most varied kind, such as abnormal, ill-cooked, or improperly digested food, toxic products of digestion, and irritant drugs or poisons, often cause enteritis, though not so frequently as in the corresponding affection of the stomach. Of these, improper food is by far the most common, especially during the first year of life. Among the most important of the causal agents of this group are the alkaloids or ptomaines and certain albumoses which result from the putrefactive decomposition of proteids either before ingestion or afterwards. These substances appear to be the determining factor in certain severe, and often fatal, forms of enteritis (see FOOD-POISONING). Certain irritants, such as corrosive sublimate, used as lotions or injections, have been known to produce enteritis—even fatal—without direct introduction into the alimentary canal.

Specific forms of intestinal inflammation are determined by various micro-organisms and their products, and to such causes may be referred cholera, dysentery, typhoid fever, and probably many cases of 'summer diarrhoea' or cholera infantum, all of which are primarily varieties of enteritis. Some of the normal micro-organisms of the intestinal canal appear under certain conditions of their environment to be able to assume pathogenetic powers (see *BACILLUS COLI COMMUNIS*). Many cases of food-poisoning have been known to be due to the *B. enteritidis* and *B. botulinus*, with which meat may be infected though itself giving no evidence of putrefaction or unsoundness.

2. Exposure to cold may be followed by inflammation of the intestines, as it may be by inflammation of the lungs, kidneys, or pleura. See CHILL.

The occurrence of inflammation and ulceration of the duodenum which occasionally follows extensive superficial burns cannot be altogether explained by the hyperæmia of the intestines, which is said to follow the superficial injury; but whether the cause be embolic, or the elimination by the bile of some irritant poison, is unknown.

3. Wounds, new-growths, volvulus, intussuscep-

tion, herniæ, impaction of feces, gall-stones, and parasites, will lead to enteritis.

4. Inflammation of neighbouring parts may involve the intestines by extension, as from the stomach, peritoneum, or bile-ducts.

5. An inflammatory state of the intestinal mucous membrane occasionally accompanies or follows the exanthemata; and it sometimes complicates septicæmia, particularly when this is of puerperal origin.

ANATOMICAL CHARACTERS.—It probably never occurs that the whole length of intestine is the seat of inflammation, and it is not often that even the entire small intestine is so affected. It is far more frequent to find certain tracts, of a few inches or a few feet, involved. Speaking generally, the colon, cæcum, rectum, duodenum, ileum, and jejunum are attacked, as regards frequency, in the order named. In some situations special features are present, but the essential characters of inflammation always exist, whatever be the site.

Owing to the physical properties of the intestinal tissues, and the rapid onset of softening and putrefactive changes, the appearances seen after death by no means necessarily correspond to what actually exists during life. Thus, the hyperæmic state of the mucous membrane, with the increased redness, varying from a more intense pink than normal up to a deep dark red, may leave but a trace *post mortem*, the vessels having become considerably emptied from the constriction of the vessels in *rigor mortis*. An increased vascularity, however, is one of the important features of the state under consideration, and it may sometimes be so intense as to lead to capillary rupture and formation of petechiæ in the mucous membrane. The tissue-elements of the gut, as a result of the irritant causing the inflammation, with the accompaniment of an increased vascular supply, undergo changes in their appearance and behaviour. Thus the epithelial cells are in a state of cloudy swelling, and leucocytes transude into the tissues from the vessels. Should the inflammation assume a suppurative character, collections of pus (abscess) may form in the thickness of the intestine, and ultimately burst on the mucous surface or into the peritoneal cavity. In all cases there is some cedema of the intestinal walls from serous effusion, and the free surface of the membrane is covered with a glairy mucus, containing leucocytes, and frequently crystals of triple phosphate. The epithelium of the follicles of Lieberkühn becomes extremely granular, and proliferates extensively, with the frequent result of blocking up the lumen of the gland, which thus becomes very prominent; or the epithelium may loosen and fall out, leaving well-defined empty pits, particularly if the examination of the mucous membrane be delayed long after death. The solitary and agminated glands are invariably much swollen, and very often the process of inflammation is most intense in their vicinity. Occasionally the mesenteric glands are similarly affected.

How this inflammation may terminate very much depends on the cause and extent; it may subside, and the bowel gradually assume its normal characters with no impairment of function; it may lapse into a chronic state; or it may pass on into ulceration, or even sloughing and gangrene.

To these various degrees and varieties of the inflammatory state different terms have been applied.

Catarrhal Enteritis (muco-enteritis).—The essential characters of this are an excessive mucous secretion, with desquamation of the epithelium. The submucosa may be infiltrated with leucocytes, but it usually remains normal, as also the muscular coat, unless the morbid condition be prolonged. Complete recovery generally takes place, but atrophy with considerable destruction of villi and Lieberkühn's glands, leaving the surface smooth and bare, not infrequently follows, especially in children. There is often some superficial erosion or simple ulceration. This form of inflammation involves great lengths of the canal, and is more common in the colon or ileum, less so higher up. See COLITIS.

Suppurative.—This term denotes a more severe form of inflammation, in which there is a formation of pus in the submucosa which may permeate all the coats. This is a very rare condition, and affects only a short distance of the bowel, which is deep red and distended, and frequently contains a sanious fluid.

A form of enteritis to which the term 'croupous' or 'diphtheritic' has been applied is of occasional occurrence in the small intestine, and rather more frequently in the colon. It is characterised by the formation of membranous patches of varying extent which consist of the necrosed mucous membrane containing a fibrinous exudation. It denotes a very severe form of inflammation, and the neighbouring bowel is swollen and purple, and tends to become gangrenous. See p. 321.

The term *dysenteric* is indifferently applied to more than one form of enteritis or colitis. The writer thinks that it had better be limited to that form of inflammation due to the specific organism of dysentery. See DYSENTERY; and COLITIS.

SYMPTOMS.—That a considerable variation is met with in the kind and severity of the symptoms presented in cases of enteritis, is only to be expected when the great difference in degree and extent of morbid change that is met with is remembered, as well as the great variety of causes; and in a very large number of cases the symptoms are quite out of proportion to the appearances found *post mortem*. Whereas one patient may suffer from an attack of intestinal catarrh, with but a trifling array of symptoms, another may succumb within a few days. There is no one symptom or even group of symptoms that is absolutely characteristic of the disease; even the general condition of the patient is not constant. In the milder forms of intestinal catarrh there may be slight pyrexia, with thirst and quickened pulse, but these symptoms may be scarcely noticeable, and the actual existence of the condition is often assumed, without anything like proof; while, on the other hand, in the severe suppurative enteritis they are extreme, and the patient is in a state of considerable prostration.

The following symptoms, more or less marked, occur in different cases.

Stools.—Diarrhœa is in some respects the most constant symptom, though, when the affection is limited to the higher part of the canal, and space is given for the re-absorption of the excessive exudation, it may not only be wanting, but there may be actual constipation. The lower down the bowel is inflamed, the greater the liability to diarrhœa, which hence becomes a marked character of colitis and proctitis. In the severe forms of the affection complete constipation may be due to the paralysis

of the inflamed bowel, arresting the peristalsis, and allowing of the accumulation of the intestinal contents above the lesion; this is obviously more complete when the enteritis is associated with any state producing mechanical obstruction, such as intussusception or ileus.

The character of the evacuations is very variable. As a rule they are semi-fluid when diarrhœa exists; or they may consist chiefly of an almost clear liquid with a few feculent flakes; but, when time has permitted a partial re-absorption of the fluid portion, the stools become more consistent, and in cases of enteritis which are chiefly due to fecal accumulation, solid hard masses are passed.

Mucus, in greater or less quantity, is constantly present—being especially abundant in affections of the large intestine and rectum, when it is often discharged as complete tubular casts of the bowel. In catarrhal affections of the small intestine, the mucus may only occur in microscopic particles, and when considerable in amount and intimately mixed with the fæces, generally comes from the first part of the colon; motions consisting of almost pure mucus come from below the splenic flexure.

Blood is not usual except in the severer forms, unless there be ulceration or hæmorrhoids; and pus is seldom noticed unless the rectum be inflamed. Quantities of intestinal epithelium, crystals of triple phosphates, and micro-organisms, especially the *Bacillus coli*, may be detected by the microscope.

Owing to the imperfect performance of digestion or absorption, the motions are liable to contain many abnormal constituents—as fat, when the duodenum and upper part of the jejunum are involved, or even masses of food scarcely changed; and the altered characters of the intestinal contents, with the products of decomposition, are in themselves most effective in maintaining a diarrhœa. As a rule, the discharges are paler than normal, or may be even colourless; the greenish tint so often seen in the enteritis of children is due either to a pigment formed by a bacillus, or to biliverdin; in the latter case it is considered as indicating some abnormal alkaline change in the intestine, whereby the biliverdin has become altered, though the stool itself as passed is acid in reaction. Unaltered bile-pigment in the fæces is abnormal; its presence indicates catarrh high up in the small intestine, and is always associated with fluid evacuations from increased peristalsis of the ileum and colon. The odour is usually extremely offensive or even putrid, especially the white or greyish putty-like masses passed by children; though sometimes, when the evacuations are very liquid and colourless, smell may be altogether absent. See STOOLS.

Owing to a large production of gases, discharges of flatus are of very frequent occurrence, but unless there be actual obstruction, tympanitic distension of the abdomen is not usual.

Vomiting, except in the severe forms, is not a common symptom of enteritis, unless the stomach be involved, and it is relatively more frequent in children than in adults. Short of actual vomiting, nausea is frequently complained of.

Pain and Tenderness.—Pain in itself is a most uncertain symptom, being scarcely noticeable in the milder forms of catarrh; while in colitis, the colicky, griping pains, which may or may not be relieved by pressure, are characteristic. Still more is this the case when the rectum is affected, when the straining and tenesmus constitute one of the

most distressing symptoms of the malady. When the peritoneum is involved, the pain and tenderness are marked and characteristic. Both may be generally diffused over the abdomen, or may be local in character, as over the cæcum; in a large number of cases the pain is referred to the umbilical region.

General Symptoms.—Among the more general symptoms, or those associated with inflammation of special regions, are the phenomena of the febrile state. The temperature may reach 102° F., or even higher; or in some cases it may be scarcely elevated. The appetite may be unaffected, especially if the upper part of the tract be free from the disease; while there may be complete anorexia when the reverse is the case. Thirst is of usual occurrence, and it becomes very marked when the evacuations are abundant and fluid. The tongue indicates rather the general state of the patient, and is a less reliable index of the actual state of the intestinal mucous membrane than in corresponding affections of the stomach. It may be dry, red, irritable, and glazed; or coated with a thick fur, with the edges and papillæ bright and prominent; in milder cases it is often unaffected. The urine may contain a large amount of indican, indicative of albuminous putrefaction in the intestines. The character of the pulse varies with the general state. If the pyrexia be extreme, there is the usual dry skin and concentrated urine, with a tendency towards the production of the typhoid state, which usually is reached in fatal cases. In many cases the prostration is excessive, though the mind is usually unaffected to the end, and very often there is a marked irritability of temper. Headache is of rare occurrence in enteritis. A persistent hiccough is met with sometimes. In children the disease rapidly leads to a condition of emaciation and collapse. The child lies in a languid, almost torpid, state, with the skin of the abdomen intensely hot and dry; while the extremities are cold and blue, the face is pinched, and the body generally appears shrunken. Frequently this state is interrupted by attacks of convulsions, especially if dentition be in progress; or the child is extremely fretful, and maintains an almost constant, short, feeble cry, evidently accompanied by pain.

When the disease affects the duodenum, jaundice, due to closure of the bile-duct, very often occurs. The intimate nervous relation between the rectum and base of the bladder explains the frequency of micturition so commonly associated with proctitis.

In cases of so-called 'ptomaine-poisoning' the symptoms supervene within a few hours after the meal, and run an extremely severe course, frequently terminating in death, although a great variety is to be noticed among different individuals exposed to the same cause. In addition to the evidences of a virulent gastro-enteritis, such as vomiting, diarrhoea, bloody stools, abdominal cramps, pyrexia, and later, prostration and collapse, certain nervous phenomena—convulsions, tetanic spasms, paralysis, and coma—are frequently present in varying degree.

DIAGNOSIS.—The variability and oftentimes vagueness of the symptoms frequently admit of a diagnosis of enteritis being made only by a process of exclusion. The history of improper feeding, whether temporary or prolonged, often suggests the nature of the disease; though it cannot be denied that all rules of a rational dietary are frequently

violated with apparent impunity both by children and adults.

Diarrhoea alone can by no means be taken necessarily to indicate the existence of intestinal inflammation, and the same may be said of constipation, pain, vomiting, and other single symptoms. It is rather to a group of symptoms, with the previous history, that the observer must look. The character of the stools, as already described, often indicates the region of gut affected; and the existence of extreme tenderness and pain, with a hard quick pulse, and the characteristic decubitus, point to the involvement of the peritoneum, which an exacerbation of temperature tends to confirm. The distinctive features of typhlitis, colitis, and proctitis are elsewhere described sufficiently to form material for diagnosis in most cases. To distinguish between inflammation of the jejunum and ileum is usually impossible, nor, practically, is it a matter of importance. The history of the case, the course of the temperature, and the characteristic rash and headache, as well as Widal's reaction, should serve to separate typhoid fever from acute enteritis, which is sometimes mistaken for it.

PROGNOSIS.—A simple intestinal catarrh occurring in a healthy subject certainly tends, after a few days, to complete recovery; but occurring, as it frequently does, in persons in ill-health, it is far more liable to pass into an obstinate chronic condition. In children, the opinion should be very guarded; for while in a large number of cases perfect recovery follows removal of cause and suitable treatment, others, for no very apparent reason, will, in spite of everything, progress to a fatal termination; and this is, of course, more likely to be the result where the child is weakly or the subject of other disease. The mildest diarrhoea in children suffering from athrepsia quickly becomes serious, killing as it were from rapidly supervening shock; the onset of so-called summer diarrhoea during convalescence from such diseases as whooping-cough or pneumonia is also of grave import; and in true cholera infantum, hyperpyrexia, great prostration, and especially uncontrollable vomiting, are almost surely fatal indications. Enteritis in different degrees of severity constitutes one of the most important causes, if not the most important cause, of infantile mortality.

In the severer forms of enteritis, as they affect adults, opinion must be guided by the nature of the cause, and the general state of the patient. Recognising that the unfavourable tendencies of the disease are towards extreme prostration, to perforation with fatal collapse, or to chronic ulceration—according as these conditions are threatened, so may the prognosis be fairly made. The duration of extreme cases rarely extends beyond a few days, when, if death do not occur from cardiac failure or pulmonary complication, the symptoms abate, and recovery, with oftentimes a tedious convalescence, follows, or a chronic condition of disease is established.

TREATMENT.—Although great variety exists in the degree of severity of the symptoms of acute enteritis, and a corresponding difference obtains in the treatment to be pursued, yet certain general principles may be first laid down, and the more special details adapted to certain conditions afterwards indicated. Inasmuch as the disease is one where the organs concerned with the preparation of the food are those mainly at fault, every effort should be made to minimise the bodily waste. This is best attained by keeping the patient in bed, which also offers

the additional advantage of providing a uniform warmth.

As regards diet, in the greater number of cases of acute intestinal inflammation the appetite is much impaired, even to complete anorexia. Provided that the person attacked have been previously in good health, no harm is done by complete abstinence from food for twenty-four or even forty-eight hours. This gives a much better chance of rest to the intestine, and a better opportunity for the removal of any irritant ingesta which may have been the cause of the inflammation. The thirst during this period may be relieved by ice-cold water, with or without a little lemon-juice. It must not be forgotten that, with the mucous membrane and its glands inflamed, the conditions of normal digestion and absorption are materially interfered with, and articles of diet that ordinarily are most nutritious and easily digested may and do become, under these altered circumstances, positively harmful. The aim in feeding the patient should be to give those materials which require the least digestion, and, being most quickly absorbed, leave the smallest amount of indigestible residue. If the stomach be implicated—and it is rare that it is not so—meat-foods are badly borne. Instead of the proteid constituents being digested, they undergo putrefactive decomposition, and thus add fresh irritants to the canal lower down. If, however, the stomach be tolerably free, then meat-essences, made thin and allowed to stand till cold, may be given. The nausea or vomiting which is usually present is more easily overcome by giving the nourishment cold; and a few drops of lemon-juice are of great service if added to the beef-tea. Milk is very uncertain in the way it is tolerated by such patients. Occasionally it is impossible to give it, the vomiting or diarrhoea being increased by it; but equal parts of milk and soda-water may constitute sufficient nourishment to last for several days in extreme cases, and may be well borne. Lime-water may be substituted for the soda-water, but, as a rule, effervescing fluids are more grateful, koumiss being often of great service. The milk should be sterilised and as free as possible from cream, for fats in all forms are to be avoided, since the products of their decomposition are extremely irritating. Beef-tea or chicken-broth made with milk in place of water may be tried with advantage. Farinaceous substances, if given at all, should be administered only in small quantities at a time; a remark which equally applies to all other food. Thinly made Benger's food or Plasmon is often most useful. Nutrient enemata are of value in some cases.

A very great deal may be done for the patient with drugs, both in the relief of symptoms and in aiding the cure.

It is seldom advisable to check the diarrhoea in acute enteritis; and an aperient to begin with, unless any evidence exist of peritonitis, is a rational treatment; thereby the irritant, whatever it may be, is removed, and a better chance for recovery is given. Improper food is so commonly the cause, that the majority of cases are benefited by a preliminary purgation. Probably the best aperients in this case are castor oil, and calomel in doses of one to four grains according to age, but it may be necessary to follow up the latter after a few hours with a quickly acting saline aperient. If the inflammation be confined to the colon, where, as already said, accumulations of feces are the common cause, copious

simple enemata, repeated every six or eight hours, are of great advantage; and this plan may be pursued in conjunction with the aperient given by the mouth. The object is to clear out the alimentary canal; and provided that this has been done, abstinence from food for twelve hours, and some bismuth in an effervescing form, are frequently sufficient in milder cases to put the sufferer on the road to cure. The writer places great reliance on bismuth, either in the form of solution with an effervescing citrate of potassium, and three or four minims of diluted hydrocyanic acid; or granular effervescing lime-juice and bismuth. The nausea and vomiting are best relieved by this treatment. For the pain, poultices or poppy-head fomentations, or the internal administration of opium, may be very effective. Should there be peritonitis, the opium must be increased in amount, with a view to giving complete rest to the bowel. Several leeches applied to the anus, to relieve the hyperemia of the intestinal tract, are occasionally necessary in extreme cases. When the attack is distinctly attributable to cold, a profuse sweating induced by hot baths, and ten grains of Dover's powder, is often of great benefit. In those cases where, from the duration, character of stools, and previous treatment, there is reason to believe that the irritating causes are got rid of, the diarrhoea may then require special treatment, especially when the patient has been in ill-health, or is constitutionally debilitated. A powder, consisting of Dover's powder 5 grains, and carbonate of bismuth 10 grains, given every six hours, is very efficacious. Vegetable astringents are frequently used for the same purpose.

When the more acute symptoms have subsided, the bismuth may be still continued, and later on given with a vegetable bitter, such as calumba. Ten to fifteen minims of the diluted hydrochloric acid in an ounce of water much assist recovery of the digestive power of the stomach, for which purpose also pepsin is valuable.

In consequence of the great liability to a second attack which this disease engenders, avoidance of well-known harmful articles of diet, and the use of warm clothing or flannel belts, are demanded as a prophylaxis.

In infants and young children the great liability to collapse, often rapidly fatal, must be borne in mind. Stimulants in some form are almost a necessity. The following prescription may be employed: *Liquoris Bismuthi et Ammonii Citratis* mj-ij, *Spiritus Ammoniae Aromatici* mj-v, *Tinctura Cardamomi Composita* mj-v; *Aqua* ʒj-ʒij—according to age. Brandy in small quantities is often the means of saving life in these cases. When the collapse is not threatening, one or two drops of the official solution of corrosive sublimate, with half a fluid-drachm of syrup, and a fluid-drachm and a half of water, every two or three hours, may be of great service. It is a more convenient mode of giving mercury than in the form of Grey powder. But in one form or another the writer believes mercury to be of prime necessity. Corrections of diet on the lines indicated above are of course essential. Hot baths and other means to keep the child warm must be employed.

In the severer cases, which are lapsing into the typhoid state, the general principles for that condition must be followed; but, except in such a state, alcoholic stimulants are rarely called for.

Inasmuch as there is good reason to believe that

many cases of intestinal inflammation, especially those of an epidemic character, are due to the activity of micro-organisms, the treatment of the disease on antiseptic principles has naturally been suggested. The problem has been to find a germicide which should pass to the ileum and colon without itself undergoing decomposition in the mouth, stomach, or upper part of the intestine, and should at the same time be harmless to the patient. Many are the agents which have been proposed, and with varying success. Few, if any, are superior to calomel or corrosive sublimate, or the solid preparations of bismuth. Thymol and salol are occasionally useful, but these latter, like resorcin, salicylic acid, salicylate and benzoate of sodium, salicylate of bismuth and cerium, the sulpho-carbolates of sodium or zinc, creosote, naphthalin, iodoform, and peppermint, are far more efficacious in checking fermentation in the stomach and upper bowel. Whichever remedy be employed, it should be given in frequently repeated small doses according to age. Irrigation of the colon by copious enemata of water, containing small proportions of one or other of the above-mentioned substances, is an effective method of intestinal antiseptics.

(B) Chronic Enteritis.

ÆTIOLOGY.—1. A certain proportion of the acute cases become chronic, the original cause persisting.

2. Those conditions which lead to a chronic state of congestion of the intestinal tract will thereby so affect the constitution of the tissues, with a consequent disturbance of function, as to constitute a chronic inflammation. The most important of these conditions is obstruction, either at the right side of the heart, or affecting the portal circulation in the liver.

3. Chronic enteritis is the occasional accompaniment of some general chronic disease, such as Bright's disease, when deteriorated blood may be regarded as leading to a chronic inflammation.

4. Residence in tropical climates is a not infrequent cause of lasting inflammatory disease of the bowels.

ANATOMICAL CHARACTERS.—The intestinal mucous membrane, when it has been the seat of chronic inflammation, is generally thickened, tough, and of a grey colour, from a deposition of pigment, due to the chronic congestion. The epithelial cells are cloudy and ill-defined, and there is a round-celled infiltration of the mucous and submucous layers passing into the stage of connective tissue; hence the thickness and toughness. This fibrous hyperplasia is often localised as polypoid elevations with intervening areas of atrophic mucous membrane. The lymphoid follicles are prominent and hard; the intestinal glands are frequently blocked with cells and secretion, and form minute solid perceptible masses, or are atrophied or even cystic; and the villi of the small intestine are shrunken and stunted. The surface of the membrane is more or less covered with a viscid glairy mucus, containing pus and imperfectly formed epithelial cells; not infrequently such mucus may be voided in the form of membranous-looking shreds or even complete casts of the tube, and this is particularly the case in the pellicular form of colitis (*see* CASTS). Sometimes the muscular coat is thickened from formation of connective tissue. As a rule, therefore, the bowel is increased in thickness; but in children it not infrequently happens that a chronic enteritis is associated with an atrophy of all the coats and the con-

tained glands, the tube being much thinned and parchment-like, and of a slaty tint. It is unusual for a chronic inflammation of the intestine to exist in adults without coincident ulceration, which is often most extensive; but in children the disease may proceed to a fatal termination, and show no such condition after death.

SYMPTOMS.—It is not always easy to say exactly when an acute case has lapsed into a chronic state, very much the same symptoms being continued. In such affections of the small intestine, the diarrhoea may be wholly wanting, and the bowels may be very confined. This is due to the diminished peristalsis, from impaired irritability of the muscular coat. When, however, ulceration is extreme, and especially if it be the colon or rectum that is mainly affected, chronic diarrhoea is an invariable symptom. The remarks made on the character of the stools in acute enteritis are equally applicable to the chronic state, with the addition, that solid and liquid evacuations frequently alternate. Lasting as the disease often does for many months or even years, a general impairment of nutrition results. The functions concerned in the elaboration of the food, as well as that by which the digested products are absorbed, are necessarily perverted. The marasmus is speedily noticed in infants and children, whose growing tissues less readily withstand malnutrition. Apart from the general ill-health produced, the mental qualities become affected, so that the intellect may become dulled and sluggish, the temper irritable, and the patient may fall into a condition of marked hypochondriasis; this is particularly liable to be the case when the colon is the seat of the disease. The emaciated appearance; the dirty muddy complexion; complicated often with a short dry cough, dependent on reflex irritation from the stomach, frequently lead a superficial observer to suspect the existence of phthisis. *See also* COLITIS.

PROGNOSIS.—Chronic enteritis almost invariably tends towards a fatal termination, though this may be long delayed. The general nutrition becomes more and more deranged; and death from inanition finally terminates an existence of prolonged suffering and discomfort.

TREATMENT.—Owing to the unfavourable tendency of this disease, the treatment can be rarely more than palliative. The debilitating and wearying character of the malady emphatically calls for good feeding. The diet should be abundant and nutritious. During the exacerbations of membranous enteritis, the giving of food is often difficult owing to the vomiting and pain produced; in such cases koumiss is of great value. When the disease affects the large intestine, the ordinary digestive changes in the food have taken place, and the contents of the canal reach the colon in the normal semi-fluid condition; in this state they may be passed; but owing to the impaired movements of the affected bowel the feces are apt to accumulate, and constipation results. This should be guarded against by simple enemata, and the soothing effect of injections of warm water only is often very marked. Distinct benefit has been known to follow hydrotherapeutic treatment, especially if accompanied by free rectal injection. In those cases where the enteritis is a sequel of a congestion of the intestine, the treatment must be directed to relieve if possible the cause of that congestion. Since this is usually some such intractable condition

as Bright's disease, cardiac dilatation, or cirrhosis of the liver, attention should be directed to the relief of these affections.

Tonics—such as quinine, iron, bark, with sea-air—are of undoubted benefit; and, so far as possible, causes of mental worry should be removed. Massage of the abdomen and gentle movements specially directed to the exercise of the abdominal muscles are most beneficial.

17. Intestines, Malformations and Malpositions of.—These may be (a) *congenital*; or (b) *acquired*.

(a) *Congenital*.—Though seldom of much clinical importance, congenital malformations of the intestines are often of great interest from a developmental point of view. The malformation may be of the nature of an *excess*. Thus certain parts of the canal—duodenum, colon, and appendix vermiformis—have very rarely been found double. The commonest of all these malformations is a diverticulum of the ileum, which may arise from the free margin of the ileum from one to three feet above the ileo-cæcal valve. The cæcal extremity of the process (which is occasionally hammer-shaped) may be connected with the umbilicus by a thin fibrous cord, showing it to be an unobliterated portion of the vitelline duct, and is commonly known as *Meckel's diverticulum*. It varies in length from half an inch to six inches, or even more; its structure is exactly that of the ileum; and it has been found the seat of typhoid ulceration, or of perforation from the irritation of foreign bodies that have become lodged therein. In very exceptional cases diverticula of similar structure have been found protruding from the duodenum, just above the opening of the bile-duct, or from the jejunum; they may even be multiple, but they are not connected with the umbilicus. The vermiform appendix may vary from half to twice the natural size.

Deficiencies of development may affect the whole alimentary canal, or only certain parts. Andral records a case where only a straight tube joined the rectum and oesophagus. The ileum may open upon an ectopic bladder. The rectum may end in a cloaca common to the urino-genital organs, or in either the bladder, urethra, or vagina. The bowel may terminate in a closed extremity anywhere between the brim of the pelvis (the rectum being generally represented by a fibrous cord, though even this may be wanting) and the anal region immediately beneath the skin; the anal pouch, which develops from without inwards, is in the latter case absolutely wanting; and all degrees between this and a pouch that has just failed to establish a junction with the rectum may be met with, producing the lesion known as *imperforate anus*. The valvæ conniventes are sometimes wanting, or very imperfect, over varying areas of the small intestines. Congenital constrictions of different parts of the canal are occasionally met with—in the duodenum, either close above the opening of the common bile-duct or at the junction with the jejunum; in the lower end of the ileum, where some abnormality in the closure of the vitelline duct appears to be the cause; or in the sigmoid flexure. Such constrictions may be multiple and of very short extent, the canal being much dilated above, and extremely narrowed and shrunken below. The ileo-cæcal orifice has been seen contracted to the diameter of a

small cedar-pencil. The cause of these lesions is very obscure, though they may be occasionally accounted for by the existence of prominent valve-like folds of the mucous membrane.

Among congenital malpositions may be mentioned complete transposition of the viscera, the cæcum and ascending colon being on the left side, and the sigmoid flexure and descending colon on the right, the liver, spleen, stomach, &c., sharing in the change. Certain parts only of the intestinal canal may occupy an abnormal situation, as in the various congenital herniæ; or the displacement may be due to unusual length of the mesenteries, the cæcum and sigmoid flexure being the parts that present the most usual malpositions from this cause. Thus the cæcum may occupy the left hypochondrium or left iliac fossa, or be found in the pelvic cavity, and other parts of the canal show corresponding changes of place. The sigmoid flexure has been seen lying to the right side of the left kidney, which was situated immediately below the bifurcation of the aorta. Similar displacements are referable to adhesions, determined by intra-uterine peritonitis, which is frequently associated with syphilis.

(b) *Acquired*.—The acquired malformations include the dilatations and contractions that are associated with stenosis; and the adhesions and abnormal communications established by ulceration and peritonitis, elsewhere referred to.

Hernial protrusions of the mucous membrane through the outer coats, often very numerous, and varying in size from a pin's head to a walnut, have been seen in the colon, and less often in the small intestine, sometimes extending into the appendices epiploicæ. They are liable to become developed in cases of long-standing constipation.

The malpositions which the intestines may come to present from changes set up after birth are so variable as scarcely to admit of classification. Hernia, both external and internal, volvulus, and intussusception are among the well-recognised displacements; but there is scarcely any limit to the changes in position which the traction and pressure of tumours and the effects of peritonitis may produce. See **INTESTINAL OBSTRUCTION**; **HERNIA**; and **ENTEROPTOSIS**.

When any symptoms are produced by malformation or malposition of the intestines they are usually those of obstruction, and can only be dealt with surgically. See **INTESTINAL OBSTRUCTION**; and **ANUS, Diseases of**.

18. Intestines, Neuroses of.—Disturbances of the sensory, motor, and secretory functions of the intestine when of primary nervous causation constitute the intestinal neuroses.

1. *Sensory*.—Under normal conditions the several activities of the canal are performed without giving rise to any conscious sensation, nor does excitation of the mucous membrane by mechanical, thermal, or chemical stimuli give rise to pain. Stimulation, however, of the central end of a divided splanchnic nerve does cause pain, doubtless due to the contained myelinated fibres of the afferent spinal roots. As compared with the stomach, the intestine is certainly less liable to be the seat of painful affections, as witness the difference in cases of ulceration of the respective viscera. Nevertheless, severe enteritis, obstruction, and new-growths are frequently, and indeed usually, asso-

ciated with some pain. Further, when the peritoneum becomes involved the liability to pain is much increased. The commonest form of intestinal pain is that denominated *colic*, in which the idea of a painful muscular spasm is involved (see COLIC). Whether any lesion limited to the mucous membrane is capable of exciting painful impressions is uncertain, and equally obscure is the existence of a true neuralgia of the intestines (enteralgia), although the occurrence of pain in the bowels, often severe, is a well-recognised symptom in the course of hysteria, neurasthenia, hypochondriasis, and sometimes also in such definite maladies as *tabes dorsalis*. In all such cases the symptoms are identical with those of colic, and the treatment is the same.

2. *Motor*.—Paralysis of the bowels. A paresis of the intestinal movements may be brought about by causes acting (1) through the *nervous system*; or (2) through imperfection of the *muscular tissue*.

(a) *Nervous*.—Cases are recorded in which the intrinsic ganglia and nerves of the intestinal muscular coat have been the seat of degeneration, but the symptoms dependent thereon are doubtful, beyond atrophy of the muscular coat. Certain lesions of the brain are accompanied by symptoms of intestinal paralysis, but with no hitherto recognised regularity, and it is assumed that such lesions act by interfering with the function of the vagi. It is doubtful how far disease of the spinal cord produces actual paralysis of the intestines, though constipation may result, a circumstance that may be explained by assuming an interference with the centre that controls defecation. See DEFÆCATION, Disorders of.

(b) *Muscular*.—The irritability of the muscular tissue may be much weakened by degeneration (cloudy, fatty, or amyloid). Inflammation of the mucous or serous coat, especially the latter, is liable to determine granular change in the muscular fibres, which, aided by a co-existent œdema, largely impairs the contractile power of the tissue. Chronic congestion of the bowel leads to the same result. The irritability is also liable to be lessened by habitual constipation, as also from the over-stimulation of too powerful and too frequent purgative medicines taken for the relief thereof; and the muscular fibres of a much-dilated portion of the bowel are apt to become paralysed from distension and stretching. The general want of tone that the muscular and nervous systems manifest subsequent to debilitating diseases, or from want of food, hysteria, and other conditions, also finds expression in the alimentary canal, in diminished peristaltic action.

Certain astringent drugs produce their effect possibly by diminishing the excitability of the nervous system, as appears to be the case with opium. Lead, which would seem to cause both paralysis and spasm of the muscular coat, may act on the nerve-terminals or on the muscular fibres.

The prominent symptom of intestinal paralysis is constipation, though other signs of obstruction, such as vomiting and meteorism, may be super-added. See CONSTIPATION; and INTESTINAL OBSTRUCTION.

Treatment is, as a rule, directed to the primary cause, but great benefit has followed the application of electricity to the abdominal parietes. Massage applied on systematic principles is of undoubted service.

Increased peristalsis; spasm.—The irregular and forcible movements of the bowels, usually accom-

panied with pain, are known as *colic*. See COLIC.

The specially painful spasm of the anal sphincters and lower portion of the rectum, termed *tenesmus*, is usually associated with ulceration and other lesions in that locality.

An over-excitible condition of the intestinal neuro-muscular apparatus may show itself as an exaggerated peristalsis producing diarrhoea. Such a state is prone to occur in neurotic subjects or in emotional states. In some persons the muscular irritability is so much increased that the mere taking of food is sufficient to induce an action of the bowels. The intestinal crises of *tabes dorsalis* are extreme cases of this class.

The bromides, arsenic, and salicylate of bismuth are the most useful drugs in this condition.

(c) *Secretory*.—Although nothing is positively known as to the nervous control over the secretion by the intestine, experiments would indicate that under certain states of nerve-stimulation the flow may be much increased; and clinically in most of these conditions of 'nervous diarrhoea' there is, along with the exaggerated peristalsis, an excessive amount of fluid poured out into the canal, as evidenced by the watery motions. The mucous discharges from the bowel, and mucous casts, which characterise the so-called 'mucous colitis,' are more probably of the nature of secretory neuroses than inflammatory (catarrhal) in origin. See COLITIS, MUCOUS.

19. *Intestines, New Growths of*.—These may, for the present purpose, most conveniently be divided into *malignant* and *non-malignant*—a clinical distinction irrespective of their minute structure.

(a) *Malignant growths*.—ÆTIOLOGY.—Malignant growths of the intestine, as in other situations, while not wholly unknown in the earlier periods of life, are rarely met with before the age of forty, and oftener after fifty. Statistics show a slight preponderance of occurrence in males. From an examination of 9,000 fatal cases of cancer, the relative frequency of intestinal cancer to that of all other organs was found to be as 1 to 25 (Tanchou).

Cancer of the intestine is nearly always primary, and very frequently runs its course without any secondary formations elsewhere. Occasionally the bowels are affected by extension from neighbouring parts, and this is especially liable to be the case in the rectum, when the uterus or vagina is the seat of the disease, and in the duodenum, which may become involved in an extension from the pancreas, liver, gall-bladder, or stomach. Very rarely small nodules are found in the solitary and agminated glands secondary to carcinoma existing elsewhere.

ANATOMICAL CHARACTERS.—Malignant disease may occur at any spot throughout the entire length of both small and large intestine, but is infinitely more often to be met with at certain special parts, notably the rectum, sigmoid flexure, cæcum, colon generally, and duodenum near the opening of the bile-duct; the jejunum and ileum being rarely affected. It has been estimated that in 80 per cent. of the cases of intestinal cancer the rectum is affected; in 11·5 the colon; in 4·2 the cæcum, appendix, and ileo-cæcal valve; and in 4·3 the small intestine. There is undoubtedly a predilection for those spots where any delay may occur in the passage of the intestinal contents, such as the

flexures of the large intestine, especially the sigmoid.

The greater number of intestinal growths included in the category of malignant are of the epitheliomatous type, especially the cylindrical variety, which may undergo colloid change; while the scirrhous and encephaloid are much rarer. As a rule, malignant growths commence in the mucosa and submucosa, frequently in Lieberkühn's or Brunner's glands, and then gradually involve the other tissues. *See* CANCER.

The mesenteric glands are generally affected, though often but slightly. Secondary infection is much less common than in cancer of other organs; when present, the liver and peritoneum are the usual seats. The inguinal lymphatic glands are occasionally enlarged when the sigmoid flexure is the seat of the growth.

Following the general course of these neoplasms when found elsewhere, they may undergo degeneration and ulceration, thus suffering a diminution in bulk at one spot while they extend in other directions. In the course of their development they may set up adhesions between the bowel and other parts; and two or more coils of intestine may be thus involved, and fistulous communications established between them. The colloid form is the most liable to invade the peritoneum, where large gelatinous masses may be developed.

The new-formed tissue may constitute an irregular mass of very variable size and extent, of a nodulated or of a villous appearance, perhaps partially ulcerated, and extending into the passage of the canal, producing an obstruction; or it may develop in an annular manner, involving the whole circumference of the bowel. The obstruction produced in the latter case may be extreme, even to narrowing the lumen of the tube to barely the size of a probe. The intestine above the growth may become enormously dilated while below it is contracted. The extent of obstruction may be altered by partial destruction of the new-growth by sloughing, though the subsequent cicatrices that may result will again constrict the gut.

SYMPTOMS.—For a varying time before this disease definitely asserts itself, the patient may complain of vague dyspeptic symptoms; loss of appetite; a sense of uneasiness in the abdomen, not amounting to pain, and usually increased after meals; and marked irregularity in the action of the bowels, with or without flatulent distension. There is an increasing tendency to constipation, for which the patient often takes large quantities of aperients of a drastic and cathartic character, which one by one lose their effect. The persistence and gradual increase of these symptoms, especially if there be any loss of flesh, is very significant, and should excite suspicion. Sooner or later, according to the duration of the case, the usual cachexia is established; and in the greater number of cases the patient rapidly emaciates, especially towards the end, though in cases of very short duration the wasting may not be so excessive. The emaciation depends not only on the general perversion of nutrition caused by the development of the cancer, but also on the direct influence it exerts on organs concerned in the digestion and absorption of nutriment; hence the higher up in the bowel the growth is situated the sooner is the loss of flesh determined.

The local signs and symptoms referable to the

new-growth itself are very variable in their occurrence, and often are singularly slight in comparison with the gravity of the cause. Thus pain may be completely wanting, and perhaps there is but little tenderness on pressure; when present the pain is usually of a dull character, and quite localised; although it may attain a severe degree.

The indications of the tumour produced by the new-growth are very uncertain, being often little more than an ill-defined fullness in one region, scarcely even amounting to that in the annular form of cancerous stricture; at other times presenting a distinct hard irregular mass of variable size. This last quality, being partly dependent on fæces, is very characteristic. Should the growth happen to be situated over the aorta or iliac arteries, an indistinct pulsation may be communicated to it. The percussion-note over the tumour is usually imperfectly tympanitic, from the existence of coils of intestines between it and the abdominal wall, the thickness of which will of necessity considerably modify the signs of the existence of the growth. The mass may present all degrees from free mobility to complete fixity, dependent on the nature of its seat, and also on the existence of adhesions to neighbouring parts. By pressure on veins or on nerves, œdema and pain of the lower extremities may be caused.

Symptoms of intestinal obstruction are rarely wanting, and may be the first for which the patient seeks relief. Vomiting, constipation of increasing severity, with signs of intestinal distension above the lesion, are among the most constant. The character of the vomit will largely depend on the duration and situation of the lesion, and the actual degree of obstruction. When the jejunum or lower part of the duodenum is the seat of the growth, the vomiting is more copious and constantly bile-stained, the bowel and stomach above the stricture sharing in the distension. When the obstruction is lower down, in the large intestine, the vomiting may be slight, and consist of little more than the gastric secretions, with such food as is taken, only becoming stercoraceous when the obstruction becomes complete. Occasional diarrhoea, determined by the chronic enteritis which exists, may alternate with the constipation; and rupture of the intestines, especially the cæcum, has been met with as a result of the atrophy and ulceration of the over-distended, chronically inflamed bowel. A moderate degree of pyrexia is not infrequent, due probably to septic absorption from the ulcerated growth, or to an associated enteritis. As in other forms of intestinal obstruction, the amount of urine voided is likely to be very much diminished when the stricture is high up, and the vomiting is excessive. *See* **INTESTINAL OBSTRUCTION.**

The stools may be characteristic of the obstruction, consisting of small separate masses, frequently hard and round, or flattened or in thin cylinders ('pipe-stem') if the growth be near the anus; they may be mixed with sloughed-off portions of the new-growth, or with blood that has escaped from the ulcerated surface. *See* **INTESTINE, HÆMORRHAGE FROM.**

If the peritoneum be involved, peritonitis may arise; and ascites, often considerable, is usually developed with colloid cancer. Superadded to these symptoms will be those caused by the morbid condition of any other organ that may be affected, such as the liver, bladder, or uterus.

COURSE AND TERMINATIONS.—Malignant disease of the intestines in the majority of cases progresses continuously. It is difficult to state even an average duration, owing to the insidious onset and vagueness of the first symptoms; but the greater number of cases do not go beyond twelve to eighteen months from the time when the disease is clearly established, while some may be fatal in a few weeks, and a few may last for several years.

Death may result as the direct consequence of the cachexia; or from complete intestinal obstruction, hæmorrhage, peritonitis, or other effects of the growth.

DIAGNOSIS.—An exact diagnosis is often not to be made, and the nature of the case remains throughout uncertain, if not actually as to the existence of a malignant growth, at least as to the seat of it. The insidious and ill-defined character of the earliest symptoms presents nothing diagnostic, though their progressive character and resistance to treatment would cause a suspicion, especially in a person over middle age, and in whom a gradual even though slight loss of weight is noticed. Even in the later stages, the symptoms are almost identical with those of chronic enteritis, which co-exists with the new-growth to a greater or less extent; and in the not infrequent cases in which a tumour is not to be felt, or is uncertain in its indications, the diagnosis becomes extremely difficult.

Supposing that the existence of an abdominal tumour be clearly ascertained, it is not always easy to determine its connection with the intestine, since the variability in position, in mobility, and in size (due to the accumulation, or the reverse, of fæces) precludes any diagnostic sign, although this very variability is regarded by some as almost indicative of intestinal cancer. In distinguishing between an intestinal tumour and one connected with the liver, gall-bladder, pancreas, kidney, mesenteric glands, uterus, abdominal wall, or the inflammatory thickening following a perityphlitis, an aneurysm, or a simple fecal accumulation, the history of the case, age, progressive nature of the condition, existence of tumour, signs of obstruction, and character of the stools, are the points to be considered in forming a diagnosis. Any one or even two of these points might equally indicate other lesions, but, taken collectively, they will usually justify the formation of an opinion. A rectal cancer, which is accessible to the touch or even to inspection, need offer no difficulty, but it is otherwise where it is a question of distinguishing a duodenal growth from one strictly limited to the pylorus. The vomiting in the latter case is more persistent than in the former, and there is a greater liability to hæmatemesis; but these are most uncertain signs, as also is the existence of jaundice, which often complicates the duodenal affection, from the greater chance of its involving or pressing on the bile-duct. A firm epigastric tumour, felt close to the margin of the thorax, and associated with distinct dyspeptic symptoms, may also be due to primary cancer of the head of the pancreas; in such case the symptoms of obstruction are less marked at first, but the growth will probably involve the bowel in its progress, and cause stenosis; owing to the destruction of the gland-tissue, the pancreatic juice is not secreted, and undigested fat may be found in the stools. Similar difficulties may surround the investigation of a tumour situated in the right iliac fossa. The importance of completely emptying the bowels by enemata, before finally

forming a diagnosis, cannot be too emphatically insisted on, since the signs, and in many respects the symptoms, of intestinal cancer may be simulated by a fecal accumulation due to simple atony of the colon. The anæsthetisation of the patient is also frequently necessary before the exact situation, or indeed the existence, of a growth can be determined.

TREATMENT.—The extremely rare cases of reputed natural cure of malignant disease of the intestines, brought about by sloughing of the growth and subsequent cicatrization of its site, afford no hope of our being able to imitate the process artificially, and the medical treatment remains at the best symptomatic and palliative.

The diet should be so arranged as to contain the minimum of indigestible residue, and permit the chief digestion and absorption to take place in the stomach, if it be the upper part of the tube that is affected. But in the majority of such cases the utmost disinclination for food exists, even apart from any vomiting or pain which its ingestion may produce, and hence, whatever the directions, the patient in the later stages practically takes nothing. The anorexia is frequently as marked even when the mischief is seated in the colon, and the area for digestion and absorption is uninterfered with.

In the earlier stages it may be advisable to insist upon as much nutritious food as possible being taken, either by the mouth or in the form of enema or suppository, so as to offer the most prolonged resistance to the inevitable end; but at the same time there is no slight reason for thinking that the same course favours the development of the new-growth. Preparations of iron may be given.

The symptoms dependent upon the obstruction we can do very little to relieve short of operation. Only the mildest aperients are permissible, to combat the constipation, and these should be salines with the object of rendering the fæces as fluid as possible; while the vomiting is as a rule uncontrollable, and, indeed, is often a relief.

Hæmorrhage may require special attention, the tincture of hamamelis being one of the most effective styptics. The pain may be so severe as to necessitate free administration of morphine subcutaneously; in other cases belladonna is of value in alleviating the local discomfort, and acts favourably by allaying any spasm.

The operative treatment of malignant disease of the intestine is described in the article **INTESTINAL OBSTRUCTION**.

(b) *Non-malignant growths.*—Owing to the variety of tissues that enter into the formation of the intestine, no less than to the origin of these tissues from two of the three primary layers of the blastoderm, the new-growths that may develop in connection with it are exceedingly numerous.

VARIETIES.—1. *Fibromata.*—These growths, which are developed from the connective tissue of the submucous coat, are usually of small size, frequently pedunculated, though sometimes appearing as sessile flattened nodules, of half the size of a pea, projecting into the canal. The smaller ones may be scattered throughout the length of the bowel, while the larger ones (up to the size of a walnut) are fewer in number or single, and are usually found in the rectum. They present the ordinary microscopical characters of fibrous tissue.

2. *Lipomata.*—Pedunculated growths of adipose tissue, springing from the submucous coat, are not

of uncommon occurrence in any part of the intestines.

3. *Myomata*.—Very rarely small growths are met with, chiefly composed of non-striated muscle-cells, with a variable amount of connective tissue.

4. *Vascular tumours*.—*Angiomata*.—Vascular growths are sometimes found, of an erectile character, similar to nævi of the skin.

5. *Mucous growths*.—It is to these growths that the term 'polypi' is generally applied. They essentially consist of the tissues of the mucous membrane, though differing in their vascularity, and also in their glandular elements. When these latter are excessive in amount, they are liable to present characters which connect them with malignant forms of new-growth, especially if their surface assume a villous formation. Polypi are not limited to any one part of the canal, though undoubtedly they are most common in the rectum. They are occasionally multiple, 170 have been seen in the lower half of the colon in a single case; and they have been met with at all ages.

6. *Lymphoid growths*.—*Lymphadenomata*.—Neoplasms corresponding in structure with the solitary or agminated glands, or with the lymphoid layer of the submucosa, are met with in association with these normal constituents of the intestinal wall, and quite independently of leucocythæmia. Nodular formations and diffuse infiltrations of similar structure have been met with throughout the stomach and intestines in Hodgkins's disease (lymphadenoma), but though giving rise to large masses, they produce no obstruction.

7. *Sarcomata*.—Small nodules of this type of neoplasm have been described as occurring in very rare instances in the intestine.

8. *Cysts*.—These have been rarely met with, and the contrast to their comparative frequency in the uterine mucous membrane is remarkable. Several instances are on record of congenital dermoid cysts which have been found attached to the rectum or sigmoid flexure, probably originating from the neuroenteric canal.

Cystic enlargement of the vermiform appendix, or of diverticula of the intestine, may follow on closure of their communication with the lumen of the bowels, and accumulation of fluid in their interior—*entero-cystomata*.

EFFECTS AND SYMPTOMS.—As a rule, the growths mentioned above present very little interest, unless they be situated just within the rectum and accessible to digital examination, for it is seldom that they are of sufficient size to form tumours which can be felt in the abdomen. They cannot be diagnosed, though they may give rise to certain symptoms, as, for instance, hæmorrhage from the vascular polypi and erectile tumours, or partial obstruction if they attain any size; but such symptoms are not diagnostic. One of their most striking effects appears to be the liability that the polypoid forms occurring in the small intestine have of inducing serious intussusception, from interfering with the due progress of peristalsis. Prolapse of the rectum is similarly found to be occasionally due to polypi.

TREATMENT.—No treatment can be attempted, beyond that of the symptoms which may arise; or the removal of growths within reach of the anus, or very exceptionally by laparotomy.

20. *Intestines, Paralysis of*.—See Neuroses of, p. 796.

21. *Intestines, Parasites of*.—The intestinal canal from within a very few hours after birth, to judge from the fæces, swarms with numerous forms of microbes, which, having gained entrance with the food and air, find in the canal suitable conditions for their development; although many, including numerous pathogenic forms, are destroyed or rendered inert by the acid of the gastric juice. Our present knowledge would lead to the belief that many of the species have no effect upon the human body, while others take an active share in intestinal digestion, as effective though apparently superfluous aids to the pancreatic secretion. How far any of these saprophytes, which may be regarded as normal inhabitants of the canal, may under certain conditions of the contents or excessive development, &c., become responsible for symptoms of disease (pathogenic), is not known with certainty, though it appears most probable such is the case. But it is well recognised that certain specific diseases, such as tuberculosis, cholera, typhoid fever, &c., are connected with specific organisms which, gaining admission with the ingesta to the alimentary canal, produce the characteristic symptoms of these several diseases.

Besides these obviously pathogenic organisms, there are numerous others which are more or less constantly found; of these *Bacillus coli communis* is by far the commonest (see p. 121). Most of these are anaerobic saprophytes, but their liability to become pathogenic in certain conditions of their environment has been mentioned. Among other more commonly met with forms are *Bacillus lactis aërogenes*, *Briege's bacillus*, *Bienstock's bacillus*, *Bacillus pyocyaneus*, *Staphylococcus pyogenes*, *Streptococci*, and various *Vibrios* and *Spirilla*. Some of these are frequently met with in the evacuations of patients suffering from different forms of enteritis; and it is probable that the poisonous substances which these organisms form from the intestinal contents, especially the albuminous, take a large share in the causation of the disease, or at least that many of the symptoms are to be referred to the ptomaines which are absorbed. But our present knowledge does not enable us to associate with each of the multiform diarrhoeal conditions which occur its own specific causal organism, as we can do in the case of cholera or typhoid fever.

Actinomycosis has been met with in the intestine, where it forms raised whitish patches, setting up inflammation, and proceeding to abscess, which may burst into the peritoneum or present at the integuments. As the disease spreads, some healing may take place. See p. 22.

The *Bacillus anthracis* also occurs in the intestine, causing swollen oedematous patches of the mucous membrane, which are intensely congested and rapidly slough. The intestinal lesion may be primary, or it may be part of a general infection. See PUSTULE, MALIGNANT.

A few species of the yeast-fungi or saccharomycetes, such as *torule*, and of the hyphomycetes or moulds, such as the *Oidium albicans* or 'thrush,' occasionally develop in the intestines. See STOOLS.

Various species of animal parasites, which mostly obtain their nourishment from the contents of the canal, are met with in the intestines. The majority of these organisms, with the symptoms they give rise to and their treatment, are described under ENTOMOZOA.

22. Intestines, Perforation and Rupture of.—**ÆTIOLOGY.**—The causes of perforation or rupture of the intestines may be arranged thus : (1) *External injuries*, such as blows, being run over, &c., which, though more liable to rupture the solid abdominal viscera, frequently cause laceration of the intestines, especially the ileum or jejunum.

(2) *Corrosive poisons*, when swallowed in any considerable amount, may destroy not only the walls of the stomach, but also those of the upper part of the intestines.

(3) *Extreme distension by flatus or feces* above the site of a constriction may cause the bowel to burst. It is the cæcum which usually gives way in chronic obstruction in the colon or rectum.

(4) *Ulcerations*, pre-eminently the so-called peptic ulceration, and less commonly typhoid, tubercular, and catarrhal ulceration, may lead to intestinal perforation. See APPENDICITIS.

(5) *Perforations* may be produced *ab extra*, by the bursting of abscesses or aneurysms into the canal.

SYMPTOMS.—The most striking symptoms which perforations of the bowel present are a sudden attack of severe abdominal pain, followed by vomiting and collapse; and it is a noticeable fact that rupture of the hollow abdominal viscera is more liable to induce this condition than a similar lesion of such organs as the liver or spleen. Rigors are of occasional occurrence at the onset, and the pulse is quickened, with sometimes a rise in temperature.

Should the patient live twenty-four hours after the establishment of a perforation, signs of peritonitis will assert themselves—severe abdominal pain and tenderness, pyrexia, vomiting, and other symptoms. Supposing that the perforation follow an ulceration in the course of a previously high temperature, such as enteric fever, there is sometimes, though not always, a sudden and considerable fall in the body-heat; this, with the acute pain, may be the first indication that perforation has taken place.

Perforation or rupture of the intestines usually proves fatal within forty-eight hours of its occurrence, although cases are recorded which have lasted for weeks; very rarely recovery has taken place. Occasionally a localised abscess may result.

There are no reliable signs whereby rupture of the stomach may be distinguished from that of the intestines.

TREATMENT.—Rest is of primary importance, in regard both to the whole body and the bowels themselves. This object is best attained by the free use of opium, commencing with a grain, and repeating it in a few hours until its influence is fully established. It is also desirable to stop all food, except an occasional teaspoonful of meat-essence; to give ice to suck; to administer nutrient enemata, and brandy and ether subcutaneously if the collapse be profound; and to apply warmth to the extremities. Resection of the ruptured portion of the bowel, with suturing of the divided ends, and washing out of the peritoneum, has been performed with success, and should be attempted in all cases seen soon after perforation has taken place.

23. Intestines, Spasm of.—See p. 797.

24. Intestines, Syphilitic Disease of.—The intestinal canal is rarely the seat of the specific lesions of syphilis, except at the lower end of the rectum, and margin of the anus. Small gummata

have been found in the submucous tissue of various parts of the bowel, and sometimes the ulcers to which these growths give rise by their degeneration and breaking down; radiating fibrous thickenings and cicatrices of the mucous membrane have also been seen in syphilitic subjects, sufficient even to cause obstruction. It is doubtful whether there be any specific ulceration of the intestine which is not preceded by gummata, although small ulcers do occur in new-born children, the subjects of congenital syphilis.

Syphilitic ulceration and stricture of the rectum are not of infrequent occurrence, the former especially in women. See RECTUM, Diseases of.

25. Intestines, Tubercular Disease of.—

ÆTIOLOGY.—As a primary disease, tuberculosis very rarely attacks the intestines in adults, though it is of very frequent occurrence in children as part of a general tuberculosis, or possibly from the consumption of milk from tuberculous cows. In adults, on the contrary, tubercular disease of the intestines is very commonly developed secondary to a similar affection of the lungs, due probably to the swallowing of the sputum.

ANATOMICAL CHARACTERS.—The submucous layer and the peritoneal coat are the structures in which the tubercle originates; in the former situation it especially favours the ileum and cæcum, although it may develop throughout the entire length of the tube, while the peritoneal tubercle is about equally distributed. The mesenteric glands are always considerably involved. The rarity with which the stomach is affected by tubercle is in marked contrast to the frequency of the intestinal lesion.

In cases of acute tuberculosis in children, death may take place before any changes in the tubercular formations have taken place, and countless grey granulations, from the size of a pin's head to bodies quite microscopic, are to be found in the submucosa, and in the solitary and agminated glands. Later on, however, these non-vascular new-growths coalesce, and form distinct masses, which from lack of nutrition undergo caseous degeneration and break down, thus forming the tubercular ulcers. The ulcers tend to spread, and rarely to heal, and while they may be at first limited to the glands, they invade the adjacent mucous membrane, spreading especially in a direction round the bowel, their extension being preceded by the development of fresh tubercles, chiefly along the course of the main blood-vessels. Large masses of the mucous surface may be thus destroyed, leaving a ragged, flocculent surface, formed of the muscular fibres, or even of deeper structures, which lesions rarely proceed to perforation into the peritoneal cavity, adhesive peritonitis having established attachments to adjacent parts. The thickened, congested, irregular edges of the ulcers, with miliary tubercles close to the margin and on the corresponding peritoneal surface, are very distinctive.

SYMPTOMS.—Until ulceration be established, there will be no symptoms of tubercular disease referable to the intestinal canal; and even when this stage is reached, there are no special symptoms.

TREATMENT.—Little can be done for intestinal tuberculosis. The course of the disease is almost invariably to a fatal end, and it is very rare for healing and cicatrization to take place. The neces-

sity for feeding the patient is almost contra-indicated by the existence of a destroyed digesting and absorbing surface, whereby the food becomes a positive irritant. Such nourishment as is taken should therefore be in the most digestible and concentrated form, that as much as possible may be taken up from the stomach and upper part of the intestine. Starch and opium enemata may do a little to check the diarrhoea, but their efficacy is soon lost. Hæmorrhage, should it set in, is scarcely amenable to treatment, though astringent enemata may be of some use, combined with the internal administration of acetate of lead and opium. No treatment has as yet been effectual in arresting the spread of intestinal tuberculosis.

26. Intestines, Ulceration of.—Ulceration of the intestinal wall, from one cause or another, is of extremely common occurrence. The morbid processes involved in the production of the ulcers are in all cases essentially the same, namely, a molecular death and disintegration of the tissue, leaving a solution in continuity, of varying extent and depth.

VARIETIES: (1) Primary inflammatory ulcers.—Any enteritis, whether of the mildest catarrhal character, or of a specific type such as diphtheritic, dysenteric, or typhoid, may lead to ulceration of the bowels. As a rule, the more severe the cause of the inflammation, the greater the liability to this complication; and the same holds in respect of any intestinal catarrh, developed in the course of any serious state, such as typhus fever or Bright's disease. The ulcer may appear either as a small abrasion of the epithelial layer, which gradually extends and deepens until the whole mucosa is involved; or the first indication may be a thin glairy pellicle, adherent to the mucous membrane which in time is thrown off, leaving a breach in the subjacent tissue. In other cases the destructive process commences in the thickness of the bowel, either from the rupture of small collections of inflammatory products, resulting from an enteritis, or from inflammation of the lymphoid follicles. The escape of these products into the tube leaves behind an ulcer.

These lesions may be found anywhere throughout the bowels, although they are perhaps more frequent in the large than in the small intestine; and one form of follicular ulceration, associated with the specific poison of dysentery, is almost limited to the former situation. The colon is also the seat of a very extensive simple ulcerative colitis, in which the mucosa is destroyed over large areas, but which does not commence in the follicles (*see COLITIS*). At those places where any delay is likely to arise in the passage of the fæces—the cæcum, sigmoid flexure, and rectum—and at those spots which are most prominent, such as the edges of the valvulæ conniventes, and the sacculi of the colon, where an enteritis is most likely to be produced, there will be the probable site of inflammatory ulcers. The specific ulcers of dysentery and typhoid fever are described elsewhere. In cholera, ulceration of the lower end of the ileum and colon is sometimes met with.

(2) Ulcers resulting from the separation of necrosed tissue.—The process of molecular disintegration which takes place along the line between living and dead tissue, resulting in the separation of a slough and the leaving of an ulcer, takes place in the intestines as elsewhere. The causes leading to the death of circumscribed areas of tissue are various.

Sometimes the vitality of a portion of the mucous membrane is destroyed by degeneration, such as the lardaceous, and an ulcer marks the spot of the removed patch, which usually occurs in the ileum or colon. More frequently, as in Bright's disease, obstructions of the portal system, or plugging of the mesenteric arteries, the local death is induced by capillary hæmorrhage or a cessation of blood-flow through a limited area. Under such circumstances the solvent power of the digestive juices may be exerted on the non-living tissues, which are thus removed, and an ulcer is left. To such ulcers the term *peptic* has been applied, and identical lesions are met with in the stomach. They almost invariably occur in the first part of the duodenum, above the point of entrance of the alkaline bile and pancreatic juice, although very rarely they have been seen in the jejunum. Ulcers of this character appear to be occasionally connected with large superficial burns, but how the relationship is established is not known. It is a singular fact in regard to them, that they are three times more common in men than in women, which is quite the reverse of what obtains in the stomach, although the relative frequency of gastric and duodenal ulcers is estimated as thirty to one.

(3) Ulceration of new-growths.—Almost any neoplasm of the intestinal wall may ulcerate, though as a rule the more rapidly developed forms are the more liable.

CHARACTERS.—The appearances presented by the various ulcers differ with the cause and the duration.

They may be single, as is generally the case with the duodenal ulcers; or innumerable, as the follicular ulcers of the colon. Typhoid and tubercular ulcers are as a rule multiple, and are most numerous at the lower end of the ileum, where the agminated glands are most abundant. Occasionally large surfaces of the mucous membrane are destroyed, with here and there small isolated spots of the membrane left, due to the spread and coalescence of many separately arising ulcers. In dysentery and chronic tubercular ulceration this is especially liable to happen. Many of the catarrhal and follicular ulcers are extremely small, not more than a line in diameter.

The peptic ulcers are distinguished by their very definite, 'clean-punched' appearance; the edges are slightly sloping, and but very little, if at all, thickened; while the mucous membrane immediately adjacent has a perfectly healthy appearance. In most of the other varieties the edges are thickened, irregular, and shaggy, frequently excavated and undermined, the ulcerative process extending beneath the mucous membrane, which gradually dies and sloughs away as its nutrition is cut off. Dependent upon the depth and course of the ulcer will be the nature of its base, which may be formed of the muscular coat, of the peritoneum much thickened, or of adjacent structures with which adhesion has been established, such as the liver or abdominal wall. The floor of ulcerated tubercular deposits and malignant new-growths usually presents small nodules which are being developed coincidently with the ulceration. The buff or ash-grey pigmented sloughs, partially separated, give a characteristic appearance to the old-standing ulcers of dysentery and tuberculosis. The tubercular and typhoid ulcers of Peyer's patches present a certain difference in the direction in which they extend: though at first both are limited to the patch, the former tend to spread in an annular manner, whereas the latter have usually

their long axis corresponding to the length of the bowel. This difference depends rather on the duration of the ulcer than on any specific distinction due to the two diseases; for the more acute typhoid lesion rarely spreads much beyond the area of the patch, which is in the long axis of the bowel, while the chronic tubercular ulcer follows the distribution of the lymphoid tissue outside the patches, and particularly along the course of the blood-vessels and lymphatics.

COURSE.—The course of an intestinal ulcer may be acute or chronic, lasting a few days or for years. Some of the simple ulcers of an acute intestinal catarrh belong to the former group; while the ulceration that accompanies chronic enteritis may be of indefinite duration.

The acute forms may either heal or go on to perforation; in the former case their existence can only be inferred, and catarrhal and follicular ulcers belong to this category. The peptic and typhoid ulcers are those most liable to perforate the bowel. The peptic duodenal ulcers appear to be more prone to perforate than the corresponding lesion in the stomach; but the results of perforation are said to be more likely to be localised in the former case. It is also stated that the ulcer of the duodenum following a burn less often perforates than cicatrises, and thus may lead to obstruction. Occasionally the perforation may lead to a communication between one coil of intestine and another, without any rupture into the peritoneal cavity. In chronic ulcers, where no adhesion or communication takes place, the base is thickened by a new-formed connective tissue, which is developed as fast as, or even faster than, the destructive process proceeds, and hence the intestinal wall adjacent to and involved in such ulcers is usually much thickened and indurated. Short of actual perforation or adhesion to other parts, the site of the ulceration most frequently is marked on the external surface of the bowel by a subacute peritonitis, which may produce a partial matting together of the intestines.

In the course of the healing of the larger ulcers, by the formation of a contracting cicatricial tissue, the gut may be considerably constricted, and a formidable obstruction established. But this does not necessarily follow even large ulcers, for stricture of the intestine does not follow the ulceration in typhoid fever; and the depth of the destruction would seem to influence this result. When the superficial portion of the mucous membrane only is destroyed very little contraction follows, but when the deeper parts of the wall are involved the subsequently developed cicatrix tends to shrink considerably.

SYMPTOMS.—The greatest diversity is met with in the symptoms of intestinal ulceration, and few, if any, can be regarded as characteristic. The lesion may occur without producing any symptoms; or those that do exist may be determined by the course of, or by the conditions associated with, the ulceration; or, lastly, the results of this condition, such as perforation, may entirely obscure the actual ulceration itself: it frequently happens therefore that the existence of an ulcer is not recognised. Nor may the severity of the symptoms be taken as a measure of the extent of the ulceration, for the most marked pain, tenderness, diarrhoea, and other symptoms may be produced by an area of typhoid ulceration that heals; while a perforating duodenal ulcer may give scarcely any indication of its exist-

ence, until within a few hours of a fatal ending. This course appears to be very characteristic of duodenal ulcers. The writer has recorded a case of a young man who was suddenly attacked with symptoms exactly resembling those of intestinal colic, after constipation of a week's duration; there was no vomiting and no tenderness, the pain being relieved by pressure on the abdomen. Collapse set in, and death resulted in less than twenty-four hours from the commencement of the attack. The necropsy showed a perforating duodenal ulcer. Such a case is not singular, and the fatal event may be preceded, as in this case, by nothing beyond an occasional feeling of discomfort at the epigastrium, not serious enough to call for advice or treatment.

Such symptoms as diarrhoea, vomiting, pain, tenderness, and pyrexia are as much dependent on a co-existent enteritis or new-growth, as they are upon the ulcer. Doubtless the exposed surface of an ulcer offers the opportunity for irritation resulting in increased peristalsis, but this is not of necessity, for constipation may be present. Where the area of ulceration is extensive, the absorbing surface is by so much diminished, and thus while the general nutrition suffers, the unabsorbed products of digestion are liable to decompose and induce diarrhoea. Vomiting may arise from a duodenal ulcer, but not always, and when present it may be due to peritonitis; icterus may also complicate an ulcer in this situation, by involving the opening of the bile-duct, or by extension of the duodenal catarrh. Pain may be absent or quite insignificant, unless the rectum be the seat of the disease, when the pain and tenesmus are excruciating.

The passage of blood in the stools, especially if bright, is probably an indication of ulceration low down, but it does not always occur, and it may be due to hæmorrhoids or general venous congestion from portal obstruction. Mucus is more commonly present, as discrete masses of the size of a hemp-seed or in larger quantities. *See* STOOLES; and MELENA.

DIAGNOSIS.—From what has been said, the formation of a diagnosis of intestinal ulceration is frequently impossible, and an ulcer is assumed rather than proved to exist. In enteric fever, ulceration is taken for granted as existing, though no special symptoms may indicate its presence. But if a severe and persistent diarrhoea, with liquid evacuations containing perhaps blood and shreds of mucus, and much pain and tenderness over the abdomen, supervene in a case of pulmonary tuberculosis, it is a fair inference to assume ulceration of the intestines, a diagnosis that would be confirmed by the discovery of the specific bacillus in the stools. In dysentery, as in enteric fever, the ulceration is a specific part of the disease, and the diarrhoea, pain, and characteristic stools are in this case directly dependent upon the ulceration. In distinguishing between gastric and duodenal ulcer the deferred occurrence of pain after taking food, even to three or four hours and being unrelieved by vomiting, is characteristic of the latter lesion, as well as the site of the pain being rather in the right hypochondrium, and less marked at the xiphoid cartilage and in the dorsal region, which are the frequent situations of the pain of gastric ulcer; the digestion is also much less disturbed in the duodenal affection, and hæmatemesis is much less common, being replaced by melena. The greater frequency among males has been mentioned. It is not infre-

quently difficult to distinguish this condition from gall-stone colic, the situation and character of the pain in both cases being very similar, but the duration of the pain in the latter is usually shorter and more paroxysmal, and there are usually signs of enlarged liver, distended gall-bladder, or jaundice.

PROGNOSIS.—This largely depends upon the cause. Except through perforation or fatal hæmorrhage by erosion of vessels, death does not take place from the ulceration itself. But a tubercular ulcer is not to be expected to heal, and it may by its development hasten the end of a phthisical patient. The prognosis of typhoid ulceration will almost entirely be founded on the general state of the patient, since the indications of the ulceration itself may be so slight. The ulceration of malignant new-growths may be of actual benefit, by removing portions of the mass, and so diminishing obstruction. In all cases the liability to subsequent stenosis must be remembered; and the impaired health of body and mind in chronic ulceration may continue throughout life.

TREATMENT.—Since ulcers of the intestine are inaccessible to direct treatment, little can be done for them apart from the general conditions which they may complicate, or the treatment of the symptoms to which they may give rise.

Recognising that an ulcer, when it exists, may lead to perforation, the object will be to avoid all undue movements of the intestines, and hence aperients are forbidden, and opiates are indicated. The astringents that are likely to be used for the diarrhoea or hæmorrhage may exert a local action on the lesion, and for that purpose bismuth, chalk, and the vegetable astringents, ergot or turpentine, are recommended. Intestinal antiseptics, such as salol, are often of benefit by diminishing the putrefactive decompositions which are likely to exist. Rest is probably the only element of treatment that can affect the ulcerative process directly; while any improvement of the general condition will necessarily favour the healing—objects which can be best accomplished by the use of diet of the most bland description, or of nutrient enemata.

27. Intestines, Vascular changes in.—The conditions herein included are known as *active hyperæmia* when the excess of blood is primarily at least on the arterial side of the capillaries; and *passive congestion* where the fulness is caused by some obstruction to the venous flow.

It should be remembered that even within the limits of health a considerable variation is met with in the degree of vascularity of the alimentary canal. The fluctuating periods of activity and rest undergone by the tube are associated of necessity with alternations of comparative hyperæmia and anæmia, as during the digestion of a meal or during fasting. It is impossible, therefore, to draw any line beyond which the vascular fulness can be said to be abnormal; as it is equally impossible to say exactly where hyperæmia and normal gland-change end, and catarrh begins. These states, on the border line between health and disease, stop short of producing recognisable tissue-change, and are of transient duration.

ANATOMICAL CHARACTERS.—The appearances seen *post mortem* are far from being always indicative of what existed during life. For an extreme arterial fulness may completely disappear after death, from contraction of the vessels; while venous

engorgement more or less completely remains. Submucous petechiæ and hæmorrhagic erosions are commonly to be met with in this condition.

ÆTIOLOGY.—The causes of intestinal *hyperæmia* are as follows: (a) Mechanical and chemical irritants, foreign bodies, and poisonous drugs. Spices and highly seasoned food and alcohol may bring about an abnormal degree of hyperæmia of the whole or part of the canal. These causes act locally and directly upon the vessels and are scarcely distinguished from the mildest degree of inflammation.

(b) Vaso-motor paralysis of the splanchnic area. If from any cause the normal tone of the mesenteric vessels is diminished, by inhibition or removal of the tonic influence excited by the sympathetic, the vessels dilate and hyperæmia ensues. It is in this way that diarrhoea following certain emotional states may be explained. The intimate relation which has been shown experimentally to exist between the splanchnic nerves and the vaso-motor system generally, but especially with the cardiac innervation by means of the 'depressor nerve,' whereby any considerable peripheral resistance in the systemic capillary area which impedes the action of the heart is compensated for by a dilatation of the mesenteric vessels, renders it probable that an undue hyperæmia of the intestines is of very frequent occurrence.

(γ) Among less frequent causes of intestinal plethora are, the suppression of habitual discharges—menstrual, &c.; and the removal of pressure, as of ascitic fluid.

The causes of *passive congestion* are the following:

(a) A general congestion of the entire intestinal tract will be produced by any of those causes which lead to universal congestion of the tissues, as obstructive heart-disease. Pressure by tumours or other conditions on the inferior vena cava above the liver, or on the portal vein, will bring about the same result. So also will any obstruction to the portal circulation in the liver. This is by far the commonest cause of intestinal congestion, since cirrhosis of the liver, however produced, directly tends to it.

(b) A congestion of a portion of the tube occurs when any obstruction exists to the venous flow of that part, as is marked in cases of invagination and strangulation of the bowel.

The rarer conditions of embolism of branches of the mesenteric arteries, or thrombosis of the veins, will induce intense congestion of the region supplied by the occluded vessels. The resulting infarction is somewhat smaller than the actual extent fed by the vessels, owing to the free anastomosis at the periphery of the area. Sloughing and ulceration of the mucous membrane, or extensive gangrene of all the coats, is very liable to follow on this condition.

Both these conditions of engorgement are essential features of the vascular changes comprised in inflammation.

SYMPTOMS AND EFFECTS.—These conditions may of themselves give no evidence of their existence, although an excessive and sudden hyperæmia of the splanchnic area will cause a fall in the general blood-pressure with symptoms of fainting. Overfulness, just as anæmia, of the intestinal vessels leads to increased peristalsis, probably due to the deficiency of oxygen and excess of carbonic acid which attend each of these conditions.

From hyperæmia, there is an increased secretion

of mucus and other intestinal fluids, often more watery than normal, which with an increased peristalsis, induced by the same irritant that led to hyperæmia, produces a diarrhoea. Provided this functional over-activity be limited to the production of the normal secretions of the part, and increased healthy action only, the condition of hyperæmia is not exceeded; but the passage into catarrh is easy, and unmarked by any abrupt lines.

Profuse bleeding, often accompanied by severe abdominal pain, usually follows plugging of the mesenteric vessels. The more complete the obstruction to the flow, the greater will be the pressure in the veins, and so will be produced first an œdema of the mucous membrane and entire thickness of the bowel, and later an escape of fluid into the canal itself and into the peritoneal cavity, the latter being more marked.

TREATMENT.—It is seldom that these conditions are such as call for treatment. The hyperæmia is usually of a transient nature; and the cause of congestion is generally irremovable. Aperients, such as jalap and gamboge, are sometimes beneficial.

The treatment of hæmorrhage has been considered; but this and diarrhoea, when due to congestion, are, unless excessive, often beneficial, and should not be checked. W. H. ALLCHIN.

INTRA-THORACIC TUMOURS.—See **MEDIASTINUM**, Diseases of; and **THORACIC ANEURYSM**.

INTUSSUSCEPTION (*intus*, within; and *suscipio*, I receive).—A form of intestinal obstruction, in which one portion of the bowel passes into another portion. See **INTESTINAL OBSTRUCTION**.

INUCTION (*in*, on; and *unguo*, I anoint).—**SYNON.**: Anointing.—This is a method of inducing absorption of certain substances by placing them in contact with, or rubbing them into, the skin. The local application of liniments to cause counter-irritation, to relieve pain, or for any other purpose, is sometimes included in the connotation of this term.

Mercury is often administered by this method both for syphilis and for tubercular peritonitis, especially in children. Half a drachm of mercurial ointment should be smeared upon the front of the abdomen, and the part covered with a flannel binder. Every second night the child should be washed and the application repeated. In the case of adults inunction is but rarely employed in England. H. MONTAGUE MURRAY.

INVAGINATION (*in*, in; and *vagina*, a sheath). A synonym for intussusception. See **INTUSSUSCEPTION**; and **INTESTINAL OBSTRUCTION**.

IODISM.—**DEFINITION.**—Iodism is the term within which we include a variety of painful and inconvenient effects, following, under certain circumstances, the administration of iodine and its salts, but more especially the iodide of potassium.

The effects produced by iodide of potassium may be classified as follows:—

1. *On the nervous system.*—Mental depression and diminution of muscular energy are not infrequently noted in patients taking iodide of potassium; while neuralgia, tinnitus aurium, and convulsive movements have also been described. It is possible that the potassium is here the active agent.

2. *On mucous membranes.*—Much mucous irritation is occasionally observed; conjunctivitis, lachrymation, sneezing and running from the nose, frontal headache, and puffy swelling of the eyelids, closely simulating coryza, being the most common symptoms of iodism, and sometimes following a single small or moderate dose. Pharyngeal congestion, irritable redness of gums and tongue, and œdema of the glottis have also been described. These symptoms are doubtless due to the iodine.

3. *On the skin.*—The eruptions produced by iodide of potassium appear under several forms. Erythema has been observed; and small round petechial spots, situated between the knees and ankles. These do not as a rule cause any inconvenience, and are usually accidentally discovered; but Stephen Mackenzie records the case of an infant of five months old, suffering from hereditary syphilis, who died of purpura after taking two and a half grains of iodide of potassium in a single dose. See **DRUG-ERUPTIONS**.

A pustular eruption resembling acne, and sometimes so profuse as to simulate smallpox, is not very uncommon. Large projecting nodules may appear on the face, or a copious crop of bullæ, which occasionally burst and become converted into fungoid growths, varying in size from a pea to a shilling. All these rashes are more likely to be produced by small than by large doses, and it is said that the frequent use of soap and the simultaneous administration of arsenic may prevent them.

4. *On the nutritive and glandular systems.*—Patients taking iodide of potassium sometimes complain of nausea, anorexia, and a bitter taste in the mouth; but where cachectic symptoms supervene, indicated by rapid emaciation, nervous palpitation, insomnia, and hypochondriasis, a ravenous desire for food has been observed. Vomiting, diarrhoea, and diuresis have also been described. Salivation is not an uncommon symptom. A time-honoured accusation against iodine is its supposed tendency to cause atrophy of the mammae and testicles; of this, fortunately, there is no real proof, the disappearance of the testicle, which occasionally accompanies the absorption of inflammatory products in its substance, being sometimes unjustly attributed to the treatment pursued. There is no doubt, however, of the anaphrodisiac effect of potassium iodide, and it is believed that permanent loss of sexual power may result from its long-continued use.

Fortunately for the reputation of one of our most useful drugs, the graver symptoms of iodism are decidedly rare. Iodine is often badly borne where the kidneys are diseased, and, as Trousseau pointed out, in exophthalmic goitre.

PATHOLOGY.—The only reason for the occurrence of most cases of iodism seems to be an individual peculiarity on the part of the patient. But now and then a more plausible explanation may be given, when we find cardiac or renal disease coinciding with the pustular rash of iodide of potassium. Retarded capillary circulation would naturally detain the drug within the blood; while the blocking of its usual means of exit from the system might be supposed to throw the onus of elimination on the glandular structures of the skin. Hence has been derived the plausible theory that iodine-acne is produced by direct local stimulation of the sebaceous structures; but, however true this may be in the slighter cases, Thin's careful examination of the skin of a patient suffering from a bullous rash has shown

the true pathological condition to be one of rupture of blood-vessels at certain localised points, with blocking by coagula, and escape of some of the constituents of the blood into the surrounding tissues. The sebaceous elements and sweat-glands were quite unaffected, and he believes the iodic papule, the so-called acne, the bulla, and the purpuric spot, represent different stages of vascular injury.

TREATMENT.—Coryza, or any skin-eruption, suddenly occurring in a patient taking iodide of potassium, ought to be looked upon with suspicion, and treated by the immediate suspension of the drug. The slighter varieties of iodism are by no means uncommon, and may appear after a single small dose; but although ammonia has been confidently vaunted as a specific against iodism, experience has been unable to confirm this, and we should place more faith in encouraging prompt elimination by very free dilution of the remedy, which is best taken on an empty stomach about half an hour before meals. Sulphanilic acid prevents or arrests iodism (Ehrlich), and so also does atropine (Binz).

ROBERT FARQUHARSON.
SIDNEY PHILLIPS.

IRIDOPLEGIA.—Paralysis of the iris. *See* PUPILS.

IRITIS.—Inflammation of the iris. *See* EYE, AND ITS APPENDAGES, Diseases of.

IRON-WORKERS.—*See* PNEUMOCONIOSES.

IRRIGATION (*irrigo*, I water).—A method of

applying cold water as a therapeutical agent, which consists in causing it to fall drop by drop, or in a continuous stream, on one spot. *See* COLD, Therapeutic Use of.

IRRITABILITY (*irrito*, I provoke).—In physiology this word signifies the power of responding to a stimulus, as exemplified by the contractility of muscular tissue. In medicine irritability implies an undue excitability of an organ or tissue, such as of the stomach or bladder.

ISCHÆMIA (*ἰσχω*, I restrain; and *αἷμα*, the blood).—Deficiency of blood in a part, short of complete cessation of the circulation: partial anæmia. *See* CIRCULATION, Disorders of.

ISCHL, in the Salzkammergut, Austria.—A sheltered, bracing, mild, rather moist climate. Altitude, 1,560 feet. Thermal common saline baths. *See* CLIMATE, Treatment of Disease by; and MINERAL WATERS.

ISCHURIA (*ἰσχω*, I restrain; and *οὐρον*, the urine).—This word properly signifies the arrest of the secretion of urine (*see* URINE, Suppression of). It is also applied to mere retention of urine.

ISSUES.—*See* COUNTER-IRRITANTS.

ITCH.—A popular name for scabies. *See* SCABIES.

ITCHING.—*See* PRURITUS.

J

JACKSONIAN EPILEPSY.—Epileptiform convulsions characterised by a constant local onset; a limited range, tending gradually to spread; a partial or complete retention of consciousness during the earlier attacks, and often until the whole of one side is involved; and temporary weakness of the affected muscles after each attack. The convulsions are due to irritation of the motor area of the cerebral cortex.

JACTITATION (*jactatio*, a tossing about of the body, or marked restlessness).—This is a condition mostly associated with certain severe febrile diseases, but also with some nervous affections, with severe pericarditis, or as a sequel of copious uterine or other hæmorrhages. A restlessness amounting to jactitation may likewise be met with in some patients, when suffering from severe or long-continued pain. It must not be confounded with certain forms of chorea, in which a somewhat similar tossing about of the body may be encountered. The absence of pain and of marked febrile disturbance, together with the history of the patient, will enable the latter condition to be readily distinguished.

JAPANESE RIVER-FEVER.—**SYNON.**: Shima Mushi.—An acute disease limited to the island of Nippon. It occurs during harvest, is confined to those engaged in handling the crops, is not infectious, and is characterised by fever, lymphadenitis,

cutaneous eschars—followed by ulceration, a dark-red papular eruption, bronchitis, conjunctivitis, and enlargement of the spleen. The disease lasts about three weeks, and is generally followed by recovery (85 per cent.). It is believed to be due to a form of acarus resembling the ‘harvest-bug.’

JAUNDICE.—**SYNON.**: Icterus; Fr. *Ictère*; *Jaunisse*; Ger. *Gelbsucht*.

DEFINITION.—Jaundice may be defined as a yellowness of the integuments and conjunctivæ, and of the tissues and the secretions generally, from impregnation with bile-pigment.

ÆTIOLOGY AND PATHOLOGY.—All cases of jaundice may be referred to one of two classes:—

I. Cases in which there is obvious mechanical impediment to the flow of bile into the duodenum, and where the bile is in consequence retained in the biliary passages, and thence absorbed into the blood (*Obstructive Jaundice*).

II. Cases in which there is no obvious impediment to the flow of bile in the larger ducts, but obstruction in the small intra-hepatic bile-ducts, associated with and dependent upon blood-disorder (*Toxicæmic Jaundice*).

Obstructive Jaundice.—When there is any obstruction to the flow of bile through the hepatic or common duct, the way in which jaundice arises is sufficiently clear. The bile-ducts and the gall-bladder become distended with bile, which is ab-

sorbed into the blood mainly by the lymphatics. If the hepatic duct of a dog be ligatured, and the animal killed after two hours, the lymphatics in the walls of the bile-ducts are seen to be distended with yellow fluid; the fluid in the thoracic duct is also yellow, and so likewise are the intervening lymphatic glands. In patients also who die of obstruction of the bile-duct, the lymphatics of the liver are often found to contain bile. On the other hand, two hours after ligature of the common duct, the serum of blood taken from the hepatic vein contains much more bile-pigment than that of blood taken from the jugular vein, which shows that in cases of obstruction of the bile-duct, bile is also directly absorbed by the veins.

To explain those cases of jaundice in which no obvious obstruction exists, several hypotheses have been promulgated.

1. *Suppression of the Hepatic Functions.*—It was formerly supposed that the function of the liver was merely to separate the elements of bile which were already formed in the blood; and that when anything interfered with the function of the liver, the elements of bile accumulated in the blood, and the result was jaundice of the skin and other tissues. This view has, however, no real basis; and all later observations show that the liver, not the blood, is the seat of formation of bile-pigment, and that jaundice by suppression, as thus defined, is an impossibility.

Suppression of function ('jaundice by suppression') is, however, supposed to be evidenced by two other classes of facts:—(a) *Suppression of bile-secretion* with the formation of pigments other than bile-pigments. There is no conclusive evidence of any such mode of causation of jaundice. In certain conditions pigments other than bile-pigment may be formed, and may in certain cases produce some discolouration, but this is totally distinct from jaundice. In many cases of jaundice evidence of altered activity of liver-cells is forthcoming, e.g. diminished secretion of bile and increased formation of bile-pigments; but such changes cannot be regarded as denoting 'suppression' of biliary function. On the contrary, in the larger number of such cases the most marked feature is an increased formation of bile-pigment—evidence, therefore, of increased activity rather than of suppression of function. (b) *Suppression of metabolic function*, as evidenced by diminished formation of urea with appearance of leucine and tyrosine in the urine. On this point, hitherto greatly relied upon as denoting a suppression of the function of the liver, there is, as one of the writers (H.) has shown, an almost complete absence of evidence. Thus, in phosphorus-poisoning the excretion of urea remains good up to the very last. In other words, there is no evidence of suppression of liver-function as regards urea-formation, any more than there is suppression of bile-formation.

It is thus exceedingly doubtful whether this 'suppression of function,' apart from actual destruction of liver-cells, plays any part in producing jaundice. In severe toxic conditions, such as *acute yellow atrophy of the liver*, a very extensive destruction of liver-cells occurs, with a corresponding loss of function; but the jaundice in such cases is not due to the 'suppression of function,' but to antecedent and concomitant changes affecting the epithelium of the smaller bile-ducts, causing increased viscosity of bile and obstruction.

2. *Hæmatogenous origin of bile-pigment* ('Hæmatogenous Jaundice').—There is no evidence whatever to support this mode of origin of jaundice. A hæmatogenous origin of bile-pigment sufficient in degree to cause jaundice does not occur. The liver-cell, not the blood, is the seat of formation of bile-pigment both in health and disease.

3. *Increased secretion of bile with excessive absorption from the intestine* ('Jaundice of Polycholia').—Many forms of jaundice, especially those produced by poisons, are marked at one stage or other by increased flow of bile and increased excretion of bile-pigment consequent upon the increased destruction of blood they occasion. There is no conclusive evidence that jaundice may result in such cases from increased absorption of bile from the intestine. The jaundice so often met with in such cases is the result of absorption of bile from the bile-ducts in the way presently to be described.

4. *Deranged Innervation* ('Jaundice of Emotion').—There is no evidence that this is a factor in the production of jaundice, although it is commonly credited with being an important one. It is, however, possible that strong mental emotion may cause spasm and reversed peristalsis of the involuntary muscular fibre of the bile-duct and intestine at a time when the bile is flowing.

5. *Toxic and Hæmolytic Factors.*—All the evidence goes to show that there are two important factors in producing those forms of jaundice unconnected with obvious obstruction, namely (a) increased destruction of blood with increased supply of hæmoglobin to the liver, and (b) action of poisons. These factors usually co-operate, for the most common cause of increased destruction of blood is the action of poisons. These two factors are not of equal importance. The occurrence of jaundice is determined more by the character of the poison than by the amount of blood-destruction. The most intense jaundice may be produced by poisons that cause but little, or only a moderate, destruction of blood, such as phosphorus or toluylenediamin. Most of the severe forms of jaundice met with in disease—'icterus gravis,' 'malignant jaundice,' 'acute yellow atrophy of liver'—are of this character, and illustrate this point. On the other hand, intense destruction of blood may be attended with little or no jaundice: for example, the hæmoglobinuria induced by the experimental injection of water, glycerine, or arseniuretted hydrogen, paroxysmal hæmoglobinuria, and pernicious anæmia.

Toxæmic jaundice is the result of absorption, just as simple obstructive jaundice is. It is caused by changes in the epithelium of the smaller bile-ducts, and increased viscosity of bile produced thereby. The jaundice is thus in every sense hepatogenous. The chief of the changes referred to are: (a) increased formation of bile-pigment, with (b) increased viscosity of bile, consequent on catarrh of the smaller bile-ducts. The increased viscosity retards temporarily the flow of bile along the bile-passages, and for a time may arrest this flow altogether, causing complete obstruction with absorption of bile. The cause of this intra-hepatic obstruction, as has been shown by one of the writers (H.), for the most notable of jaundice-producing poisons, namely, toluylenediamin, is a catarrh of the bile-ducts extending from above downwards (*descending catarrh*), produced by the excretion of the poison through the bile (*excretory catarrh*).

Simple and Toxicæmic Jaundice.—Instead, then, of the two varieties of jaundice formerly described, one *hepatogenous* or *obstructive*, the other *hæmatogenous* or *non-obstructive*, it is necessary now to recognise all jaundice as *hepatogenous* and *obstructive*—the result of absorption of bile—the cause of the obstruction being either simple and mechanical (*Simple Jaundice*), or due to increased viscosity of bile consequent upon action of poisons upon the blood, and their excretion through the liver (*Toxicæmic Jaundice*). The latter form of jaundice, although hepatogenous and obstructive, differs from the former in its origin, being primarily caused by the action of toxic agencies, hence the title ‘toxicæmic.’ This title at once emphasises the *toxic* origin of the blood-change, and the general *toxic* character of the symptoms usually found in association with this variety of jaundice. That is to say, it occurs in toxic conditions generally, in pyæmia, remittent fever, malaria, yellow fever, snake-poisoning, &c. The jaundice in all such cases has certain *pathological characters*: (1) It appears to be independent of any obstruction to the flow of bile in the larger ducts—the obstruction, as we have seen, being in all cases intrahepatic. (2) It is associated at one time or another with the presence of bile in the stools, often with an excessive formation of bile (*polycholia*). (3) The bile-acids may be diminished in quantity—this feature being a common one in jaundice caused by poisons.

We may now proceed to enumerate the different causes in tabular form:—

A. Jaundice from Mechanical Obstruction of the Bile-duct (‘Obstructive Jaundice’).

1. *Obstruction by foreign bodies within the duct*—Gall-stones and inspissated bile; Hydatids and Distomata; Foreign bodies from the intestines.

2. *Obstruction by inflammatory tumefaction of the duodenum, or of the lining membrane of the duct, with exudation into its interior.*

3. *Obstruction by stricture or obliteration of the duct*—Congenital deficiency of the duct; Stricture from perihepatitis; Closure of the orifice of the duct in consequence of an ulcer in the duodenum; Stricture from cicatrization of ulcers in the bile-ducts; Spasmodic stricture.

4. *Obstruction by tumours closing the orifice of the duct, or growing in its interior.*

5. *Obstruction by pressure on the duct from without, by—*Tumours projecting from the liver itself; Enlarged glands in the fissure of the liver; Tumours of the stomach, duodenum, pancreas, kidney, or omentum; Abdominal aneurysm; Accumulation of feces in the bowels; Pregnant uterus; Ovarian and uterine tumours.

B. Jaundice due to Intra-hepatic Obstruction of the Bile-ducts, caused by Action of Poisons on the Blood (‘Toxicæmic Jaundice’).

1. *The poisons of various specific diseases*—Yellow fever; Malarial fever; Relapsing fever; Typhus; Enteric fever; Scarletina; Icterus gravis; Acute atrophy of the liver; Pyæmia.

2. *Animal poisons*—e.g. Snake-poison.

3. *Mineral poisons*—e.g. Phosphorus; Mercury; Copper; Antimony; Arsenic; Chloroform and Ether.

SYMPTOMS.—From what has been stated in the preceding section, it is obvious that jaundice is not

a disease, but is a symptom of many different diseases. There are, however, certain phenomena connected with jaundice, independent of its cause, which deserve to be mentioned.

1. *Discolouration of Skin.*—Next to the liver itself, the skin is the tissue of the body which becomes most deeply jaundiced; but before it becomes affected, a yellow tint is usually observed in the conjunctivæ. There must be a certain concentration of bile-pigment to produce a yellow colour of the skin; in the slighter and more temporary cases, the conjunctivæ only may be affected. Jaundice of both skin and conjunctivæ is usually observed within twenty-four hours of closure of the duct.

The colour of the skin varies from a pale sulphur- or lemon-yellow, through a citron-yellow, to a deep olive or bronzed hue. The tint varies according to the cause and its duration. In obstructive jaundice it is light at first, and increases in depth the longer the disease lasts; although in advanced cases, as already stated, the colour sometimes becomes pale, not from the obstruction yielding, but from the tissue of the liver becoming destroyed and very little bile being secreted. In obstructive jaundice the depth of tint often varies from day to day, not from any variation in the degree of obstruction, but according to the amount of bile secreted by the liver, and the eliminative activity of the kidneys. It is well to remember that what is called ‘black jaundice’ may result from any cause of obstruction—from gall-stone as well as from cancer. In these cases the greenish or almost black hue is due to the absorbed bile-pigment being vitiated and dark, or to the visage being also darkened from imperfect aëration of the blood, the dark colour resulting from a mingling of the lividity with the colour of bile. In toxicæmic jaundice the discolouration is usually less intense; it is moreover of a more temporary character, rapidly disappearing if the cause be removed, and is generally associated with grave constitutional disturbances, as is set forth in the following sections. The colour also varies with the age, the natural complexion, and the amount of fat in the individual. It is deeper in the old, the wrinkled, and the dark-complexioned, than in young persons of fair complexion, and with plenty of fat. Lastly, it is important to remember that the colour often remains in the skin for some time after the cause of the jaundice has been removed, and that then its departure may be expedited by diaphoretics and warm baths.

2. *The secretions* are tinged with bile-pigment, but some much more so than others. This is notably the case with the urine, by which the greater part of the bile-pigment is eliminated from the body, and which acquires a saffron-yellow, greenish-brown, or brownish-black hue, according to the amount of pigment which it contains. The urine usually becomes yellow before the skin, or even the conjunctivæ; and when the cause of the jaundice is transient, it may happen that the whole of the pigment is eliminated by the urine, without the skin becoming jaundiced. On the other hand, when once the skin has become yellow, it may remain so for some time after bile-pigment has nearly disappeared from the urine.

Other secretions may contain bile-pigment as well as the urine. The cutaneous glands sometimes eliminate it in such quantity as to stain the linen yellow, but the amount discharged in this way is never great. Instances have been recorded where

the secretion of the mammary glands has been tinged with bile-pigment, but they are not common. Still rarer instances have been noticed where the saliva or the tears have been tinged. It is not a little remarkable that bile-pigment is not eliminated in cases of jaundice by the mucous membrane of the respiratory passages or of the digestive tube. This is a matter of some practical importance, for, were it otherwise, the stools might contain bile-pigment even when there was complete obstruction of the bile-duct. Still, when either of these mucous membranes is inflamed, and throws off an albuminous or fibrinous exudation, the altered secretions may contain bile-pigment. Thus, when pneumonia co-exists with jaundice, there is often bile-pigment in the sputa, which may be distinguished by the nitric-acid test from the greenish or yellow colour often presented by pneumonic sputa owing to changes in the blood-pigment independent of bile. Indeed, in cases of jaundice bile-pigment may be detected in inflammatory exudations, as in the serum of a blister, before it appears either in the skin or even in the urine. It is probable that those rare cases where the saliva has been noticed to be yellow admit of a similar explanation; in many of them there has been mercurial salivation, a condition in which the saliva is not normal, but contains much albumen.

3. *A bitter taste* is not infrequently complained of by persons who are the subjects of jaundice. It may denote the presence in the blood of the biliary acids, for taurocholic acid is intensely bitter. It is at all events not due to bile-pigments, which are tasteless. Moreover, it is a common symptom in biliary derangements where there is no jaundice.

4. *Derangements of digestion*, such as flatulence, constipation, and an altered character of the motions, may be due to the absence of bile from the motions. Bile is an antiseptic, though a very feeble one, and when it is absent the intestinal contents undergo fermentation, gases accumulate in the bowels, the fæces become putrid, and from the absence of bile and the presence of fat they present a pale-drab or clay colour. Bile is also the natural stimulant of the peristaltic action of the gut, and consequently, when the supply is cut off, the bowels are usually constipated; but in some cases the putrid fæces act as an irritant and excite diarrhoea. In those cases of jaundice where there is no obstruction of the common bile-duct, the motions may be but little altered.

When bile does not enter the bowel, the digestion of fat is interfered with. Jaundiced patients dislike fat, and do not assimilate it, and the fatty matter in the ingesta may sometimes be detected in the stools. Hence, whatever be the cause of obstruction of the bile-duct, the nutrition of the body suffers: the emaciation may be slow, but it is progressive, until all the fat disappears, and then the weight of the body may remain stationary for many months. With the emaciation there is always more or less muscular debility.

5. *Pruritus*, without any cutaneous eruption, is a very obstinate and distressing symptom in many cases of jaundice. It is usually worse at night, and, by preventing sleep, may wear out the patient. It is chiefly observed in cases of obstructive jaundice. It is not due to the presence of bile-pigment in the blood, for in some cases it precedes the jaundice, and in others it comes and goes during the persistence of the jaundice. Moreover, in many

cases of jaundice it is absent throughout, while it is not uncommon in biliary derangements where there is no jaundice.

6. *Cutaneous eruptions*.—Urticaria, lichen, and boils or carbuncles are occasionally observed in connection with jaundice; and likewise that remarkable affection of the skin known as *xanthoma*, *xanthelasma*, or *vittiligoidea*. See XANTHELASMA.

7. The *temperature* is not altered in jaundice, except when this occurs as a complication of some acute febrile disease, or when there is inflammatory action in the liver itself.

8. *Slowness of pulse*.—A common result of non-febrile jaundice is retardation of the heart's action, and diminution of arterial tension. The pulse may fall to 50, 40, or even 20, and sometimes it is also irregular. This slowness of pulse is particularly noticeable when the patient is recumbent. When there has been antecedent pyrexia, the pulse usually falls on the supervention of jaundice. Slowness and irregularity of the pulse are chiefly observed in jaundice from obstruction of the bile-duct, and particularly in those common cases known as catarrhal jaundice; and accordingly they are not unfavourable symptoms, as might have been supposed. So far as the writers' experience goes, patients with this symptom invariably recover. It has not yet been explained why this condition of circulation should be present in some cases of jaundice, and absent in others. Some experiments of Röhrig have shown that the salts of the biliary acids paralyse the heart, and retard its action, while bile-pigment has no such effect. It has been shown by Wickham Legg and others that the slowing of the heart is due to the action of cholalic acid on the cardiac ganglia. Slowness of the pulse, therefore, in jaundice may indicate the presence in the blood of unchanged biliary acids; but so far there are no observations to show that bile-acids are present in the urine in these more than in other cases of jaundice. See p. 171.

9. *Hæmorrhages*.—In many cases of toxicæmic jaundice hæmorrhages take place from the various mucous membranes and into the substance of the skin. They may also occur in cases of obstructive jaundice of long standing, from any cause, when the secreting tissue of the liver has in a great measure disappeared.

10. *Xanthops* or *Yellow vision*.—In rare cases of jaundice, all white objects appear yellow to the patient. The administration of santonin internally has also sometimes been followed by yellow vision, which has ceased as soon as the colouring-matter has been eliminated by the kidneys. This fact, as well as the observation that in several cases of jaundice with xanthops the conjunctival vessels have been preternaturally distended with blood, has led to the belief that the symptom is due to a tinging with bile-pigment of the humours of the eye. On the other hand, the circumstances that the xanthops may intermit, without any change in the jaundice; that it is usually absent when there is intense jaundice of the cornea and other tissues of the eye; and the statement that it may occur in typhus fever, and in certain derangements of vision, such as night-blindness, when there is no jaundice, have led most authorities to consider it, as appears to have been proved in regard to the effects of santonin, as due to an affection of the visual nervous apparatus.

11. *Cerebral symptoms and the Typhoid state*. Patients with jaundice are often irritable in their

temper and hypochondriacal; and occasionally they are attacked with acute delirium, stupor, coma, convulsions, muscular tremors, subsultus, carphology, paralysis of the sphincters, a dry and brown tongue, and other indications of the typhoid state. These symptoms are most common in cases of toxæmic jaundice, but they also occur in cases of obstruction, usually of long standing, where all or the greater part of the secreting tissue of the liver has been destroyed. Different opinions are held as to their cause. After death no lesion is found of the brain or its membranes, and they are, therefore, most probably due to some alteration in the circulating blood. There is ample proof that the blood of the human subject may be saturated with bile for months, or even years, without any cerebral symptoms resulting.

The cerebral symptoms in jaundice are often most severe when the jaundice is slight, and they may occur in diseases of the liver when there is no jaundice. They are best explained by the knowledge which we now possess of the function performed by the liver in disintegrating albuminous matter into less complex substances, such as urea and uric acid, which are eliminated by the kidneys. When this function of the liver is arrested or seriously impaired, as in acute atrophy, metabolism is impaired; leucine and tyrosine and other toxic substances, with which we are imperfectly acquainted, accumulate in the blood and tissues.

DIAGNOSIS.—There is rarely much difficulty in the diagnosis of jaundice, but it is well to remember that certain conditions are sometimes mistaken for it. Such are chlorosis, pernicious anæmia, hæmoglobinuria, the anæmic aspect resulting from organic visceral disease (and particularly from contracted kidneys), from cancer, from exposure to malaria, from Addison's disease, or from lead-poisoning; an undue amount of sub-conjunctival fat, or an unusually dark colour of the ordinary urinary pigment, or the presence in the urine of abnormal pigments, such as those of *santonin*, *turmeric*, *rhubarb*, &c. In every case where there is the slightest doubt, it will be removed by resorting to the nitric-acid test for bile-pigment in the urine. If this gives no result, the case is not one of jaundice.

It is a more difficult matter to determine the cause of the jaundice, and yet this should invariably be the aim of the medical attendant, before forming a prognosis or proceeding to treatment.

1. In the first place it is always well to determine whether the jaundice be of the obstructive or toxæmic type. In *obstructive jaundice* the stools contain no bile-pigment, and are therefore clay-coloured. In *toxæmic jaundice* the stools almost invariably contain bile, because the obstruction is rarely complete, and it is always accompanied by an increased destruction of blood and an increase of bile-pigments. The rule is not without exceptions, and there are several sources of fallacy. The jaundice usually persists for some time after the duct has become pervious, and thus bilious motions may co-exist with jaundice which has resulted from obstruction; or, if the motions be thin and watery, they may appear to contain bile from the admixture of jaundiced urine; or, not infrequently, when the bile-duct is quite impervious, the motions are of a brownish tinge, owing to the presence of altered blood, which may closely resemble dark bile. Iron, bismuth, and charcoal also colour the motions. A tumour corresponding to the region of the gall-

bladder will favour the view that jaundice is due to obstruction of the bile-duct. Lastly, jaundice which persists and is yet slight is most probably independent of obstruction, for jaundice from persistent obstruction speedily becomes intense.

2. It is always important to note the mode of commencement of jaundice. That which appears suddenly in a person whose previous health has been good is most probably the result of obstruction of the duct by a foreign body, or it has a toxic origin. The former cause will be distinguished by biliary colic, vomiting, and clay-coloured stools, the latter by some degree of fever and constitutional disturbance. On the other hand, jaundice coming on slowly, but ultimately becoming intense, with clay-coloured stools, points to pressure on the duct from without, or to a growth in its interior.

3. A history of previous attacks of jaundice of a similar nature is in favour of a catarrhal origin, or of gall-stones. See GALL-BLADDER AND BILE-DUCTS; and GALL-STONES.

4. Pain in severe paroxysms concurring with jaundice points generally to gall-stones or cancer; more rarely to hydatids, or to an aneurysm of the hepatic artery. Cancer is distinguished from gall-stones by there being usually a history of failing health and emaciation before either the pain or the jaundice.

5. Jaundice concurring with enlargement of the liver is most probably due to cancer or cirrhosis; more rarely to pyæmic abscesses, or to amyloid liver with large glands in the portal fissure.

6. Jaundice concurring with ascites points to cancer or cirrhosis. The diagnosis of the latter will usually be assisted by the physiognomy, the slowness of the jaundice, the previous habits, and a history of alcoholic dyspepsia; while in cancer there are often darting pains, and the jaundice is usually intense.

7. Jaundice concurring with pyrexia is either secondary to some acute febrile disease; or is due to suppurative pyelophlebitis, a suppurating hydatid cyst opening into a bile-duct, or inflammation of the bile-ducts. Temporary pyrexia may also occur during the passage of a gall-stone.

8. Cerebral symptoms associated with jaundice suggest acute atrophy of the liver, poisoning by phosphorus, pneumonia, or some specific fever.

9. Jaundice in a young person, preceded by symptoms of gastric catarrh, is most probably catarrhal.

TREATMENT.—There is no special treatment for jaundice. In a considerable proportion of cases, however, it is impossible at once to determine the precise nature of the causal disease, and pending an exact diagnosis we are obliged to adopt some provisional treatment. In view of the possibly dangerous character of the disease, the patient should be confined to bed for a few days. When, after a few days, no serious symptoms present themselves, and a catarrhal condition of the larger ducts is suspected, moderate exercise may be allowed even in the open air. The clothing should be warm, but light. The food should be simple and nutritious. There is no need to rigidly exclude fatty and saccharine matter, but no excess should be allowed, and pastry should be avoided. Alcoholic beverages, especially fermented liquors, should be withheld. In some cases of long-continued jaundice considerable quantities of flesh are required, and are digested, to supply the fatty matter lost to the system by the

absence of bile in the intestine. Milk is usually well borne, and supplies fat in an emulsified form. The patient should be encouraged to drink freely warm fluids or the natural alkaline waters, as those of Vichy, as the kidneys are the chief eliminators of bile. Warm baths should be used, and occasionally the Turkish bath is of service. At the commencement of an attack a dose of calomel or blue-pill (gr. ij.) in combination with colocynth or rhubarb pill, followed by a saline aperient draught on the following morning, may be administered. Mercurials should be cautiously used as long as an uncertainty as to the exact nature of the case remains, but the evil effects of mercury have been exaggerated, and it has been determined that it diminishes, and not increases, the secretion of bile. An alkaline and bitter stomachic is often of much service, especially when the tongue is coated; 20 grains of bicarbonate of potassium or sodium, with 20 minims each of aromatic spirit of ammonia and spirit of chloroform, 5 minims of tincture of nux vomica, in an ounce of some bitter infusion, as calumba, gentian, cascarilla, or chiretta, recently prepared, may be given three times a day between meals. In some cases, when the tongue is clean, or has been cleaned by an alkali, acids appear to do good; 10 to 20 minims of diluted nitro-hydrochloric acid in an ounce of a bitter infusion should be given half an hour before meals, and taraxacum may be usefully added—20 grains of the extract, or a drachm of the succus. Aperients are in many cases required, and in most cases useful. They have the effect of lessening portal congestion, and replace the natural purgative quality of the bile. Saline aperients as a rule answer best. A drachm of Carlsbad salt in a tumblerful of warm water, or half a tumblerful of Carlsbad water, to which some hot water has been added, should be taken before breakfast, and its efficacy is increased if it is *sipped* instead of being taken at a draught. Another useful saline aperient is phosphate of sodium, a drachm three times a day in a bitter infusion. In some cases vegetable aperients answer, when colocynth, aloes, rhubarb, or cascara may be given. When diarrhoea is present, salicylate of bismuth (gr. x.), or oil of turpentine (mx. to xx.) in capsules, on an empty stomach, should be tried. When jaundice is not due to an insuperable obstruction, euonymin, iridin, podophyllum resin, and other hepatic stimulants, are sometimes useful; and when there is gastro-duodenal catarrh, ipecacuanha is often of much service. The following is a good formula: \mathcal{R} Euonymin gr. jss., iridin gr. j., ipecacuanhæ gr. $\frac{1}{2}$, pilulæ colocynthidis et hyoscyami gr. ij.; ft. pil. ; one to be taken every or every other night. For flatulence, which often is troublesome, carbohc acid, creosote, menthol, and turpentine are useful. The following pill may be employed: \mathcal{R} Aloin gr. $\frac{1}{2}$, acidi carbolici (seu menthol) gr. j., extracti taraxaci gr. ij.; to be taken night and morning. Nitrate of pilocarpine is sometimes of service in relieving the pruritus often present. One-sixth of a grain should be given subcutaneously once or twice a day. For the same symptom warm baths at night, followed by the use of a flesh-brush, are sometimes serviceable. Bicarbonate of sodium, with bromide of potassium or belladonna, sometimes affords relief. The following lotion may also relieve the itching: Diluted hydrocyanic acid $\mathfrak{z}\text{j}$., borax $\mathfrak{z}\text{j}$., water to $\mathfrak{z}\text{viij}$. When these measures fail, and the night's rest is broken, an opiate may be required. Ox-gall is

sometimes useful in supplying the place of the deficient bile. The Fel Bovinum Purificatum (recently prepared) may be given in five- or ten-grain doses in coated pills, three times a day, two hours after meals. Daily enemata of one to two quarts of water at 60° to 90° F., to be retained as long as possible, are extolled by German physicians, especially in catarrhal jaundice. It cannot be too strongly impressed that, while using these measures, the physician's aim should be to establish the exact nature of the jaundice, when the correct treatment will be more clearly indicated.

JIGGER.—A popular term employed to designate the sand-worm or sand-flea. See **CHIGOE.**

JOINTS, Diseases of.—The diseases of joints will be considered as follows: I. GENERAL CONSIDERATIONS; II. LOCAL DISEASES: (1) Cartilages, Diseases of; (2) Congenital Dislocation; (3) Immobility; (4) Inflammation, Acute, of the Synovial Membrane; (5) Inflammation, Chronic, of the same; (6) Gonorrhœal Inflammation; (7) Gouty Inflammation; (8) Tubercular Inflammation; (9) Loose Cartilages in joints; (10) Nervous Affections; (11) Rheumatoid or Osteo-arthritis, Chronic; (12) Serous Effusions; and (13) Syphilitic Disease.

I. GENERAL CONSIDERATIONS.—Diseases of the joints are classified according to the structure primarily or chiefly involved. They may commence in the synovial membrane, in the bone, or in the cartilage. Primary disease of the ligaments is rare, and is not clinically demonstrable. No form of joint-disease remains long confined to one tissue, so that when the disease is of some duration it will be found to implicate, more or less, every element of the joint-apparatus. In this article the diseases of joints will first be generally discussed; and the individual diseases will then be considered separately.

ETIOLOGY AND PATHOLOGY.—The larger articulations, those in constant use, and more especially the joints of the lower extremity, are the most frequently diseased. Thus the knee is more often the seat of disease than any other joint; the hip-joint comes next in order; and then the ankle and elbow. All kinds of joint-diseases are frequent in children and young persons. The first year of life appears, however, to be nearly exempt from these affections, and during the second year they are comparatively rare, perhaps because movement and risk of injury are at that period at a minimum. Acute arthritis, however, is occasionally witnessed during the first year of life—during even the first six months. It is unconnected with syphilis or injury; very sudden in its appearance, and rapid in course; dangerous to life; and destructive to the articular ends of the bones by suppurative disorganisation. The causes of joint-disease in general are connected either with disordered nutrition, in which case it usually assumes an inflammatory type; or with disordered function. The latter may depend on the former, or be unconnected with it. Again, the cause may be local in its origin or arise from some constitutional defect. Among the *exciting* causes, injury is by far the most frequent. This being often slight, and not followed by any imme-

diate consequences, the connection is frequently overlooked. A blow, or a fall against the edge of a table or down stairs, may readily bruise the synovial membrane in such exposed joints as the knee or elbow, without causing any external sign. A slight hæmorrhage takes place into the synovial cavity or the sub-synovial areolar tissue, and serous effusion may speedily supervene; in this manner a common variety of acute or traumatic serous synovitis is produced. But although injury is a most fertile cause of joint-disease, the articulations may sustain most severe injury without becoming inflamed. It is rare to find any serious consequences result from dislocation; the joint usually perfectly recovering itself. Penetrating wounds of the joints are always serious injuries; they often occasion acute synovitis, and, if septic changes occur, are followed inevitably by suppuration in the articulation, and danger both to the limb and life of the individual. Fractures often implicate the joint-surfaces, and prove a frequent source of stiff-joint. Plastic synovitis may be thus set up, causing adhesions; or suppuration takes place; or the callus formed for the repair of the fracture may interfere with the joint-motion. Gunshot wounds of joints often produce the severest form of inflammation, suppuration being the usual result. When joint-disease follows an injury, it is usually confined to one joint; but when joint-disease originates from constitutional causes, more than one joint is often affected; or when only one, the constitutional nature of the cause is manifested in diseased conditions present elsewhere, or by traces of inflammation in other joints due to the same cause. The development of tuberculosis in the synovial membrane and bone is a very frequent cause of chronic joint-disease.

Joint-inflammations are of common occurrence in all kinds of fever; and also as sequelæ of the exanthemata. The great frequency of polyarticular serous synovitis in acute rheumatism is well known, as also in purpura and hæmophilia, where it is complicated with blood-extravasations. In pyæmia the joints are frequently the seat of sero-purulent and purulent effusions; as they also occasionally are in scarlatina. Puerperal synovitis is a variety of the pyæmic. In typhus monarticular arthritis is frequently met with, and the hip is the joint oftenest affected. Endocarditis and polyarthritis are very often associated together, and the endocarditis may precede and give rise to the joint-disorder by embolism. The fact that multiple joint-affectations are met with both in pyæmia and in rheumatism suggests a connection, but what its nature may be is not clear. Although in articular rheumatism pus-formation is rare, we sometimes witness joint-sup-
puration in such cases; while pyæmia and metastatic abscess may originate from ulcerative endocarditis. In chronic synovitis, affecting two or more joints, the heart should always be examined, for traces of endocarditis will sometimes be found. In the exanthemata, typhus, and diphtheria, metastases in the shape of joint-inflammations more or less frequently take place. Joint-inflammation is of frequent occurrence in dysentery. With gonorrhœa a form of arthritis is associated which is called 'gonorrhœal.' Syphilis in the later stages frequently attacks a joint, the knee by preference, syphilitic deposits taking place in the bone or the sub-synovial connective tissue, but synovial effusion is not common. A suppurative inflammation of

the ends of the bone is not rare in children the subjects of inherited syphilis. In gout the joint-structures are affected; as a rule the peri-synovial tissue becomes inflamed owing to deposits of urates. Similar deposits also occur in cartilages of encrustation. The great toe is most often affected, but the other tarsal, digital, and larger joints are frequently diseased.

Some ill-understood form of vaso-motor or trophic irritation appears to occasion arthritis in locomotor ataxy. Effusion into the joint is preceded by pain; and the knee and shoulder joints are those generally affected. In some cases of the disease changes similar to those in rheumatoid arthritis have been observed, and generally in the knee, shoulder, elbow, or hip. They occur early in the disease; arise suddenly; are often monarticular; and not rarely give rise to dislocation, especially in the shoulder. These characters distinguish the disease from ordinary rheumatoid arthritis. Severe inflammation of the joints of the paralysed limbs has been observed in cases of hemiplegia. The occurrence of joint-disorder, usually synovial inflammation, is frequent in chronic disease of the spine; and it also occasionally happens in acute softening in the form of suppurative arthritis. In both cases the knee is most frequently affected.

ANATOMICAL CHARACTERS.—Joint-disease may begin as an inflammation of the synovial membrane, of the bone, or of the cartilage. Fibrous tissue having but slight tendency to inflame, it is improbable that primary disease affecting the ligaments can be otherwise than most exceptional; but these textures very soon become secondarily affected, from their intimate connection with the synovial membrane. The synovial membrane is perhaps more ready to inflame than any other tissue in the body, and in many joints it is much exposed to injury from without, while excessive joint-movement alone is sometimes sufficient to excite synovitis. Primary disease of the bone comes next in order of frequency. Cartilage is least likely to take on primary disease (*see p. 251*). Each of these tissues, however, becomes speedily affected by disease which has invaded or commenced in the other.

SYMPTOMS AND DIAGNOSIS.—The local symptoms of joint-disease have reference to *impairment of function and change in form*; together with *pain*, both local and sympathetic; and certain *physical signs*.

Impaired function.—Usually this is great in proportion to the natural mobility and importance of the joint, and most evident in the extremities. The earliest symptom in hip-joint-disease is a slight limp or halt, while in other joints mere stiffness occurs; the full range of movement is simply curtailed, before actual pain or swelling takes place. The position of maximum relaxation—namely, that intermediate between flexion and extension—is commonly assumed by diseased joints. Even in the early stages of disease, the interference with movement is often very great, amounting to a sort of vital ankylosis, produced by the action of the muscles, whose tension prevents the joint-surfaces moving upon each other—an effort to avert pain. This form of ankylosis disappears during necrosis. Muscular or vital ankylosis must be distinguished from the rigidity produced by structural changes. Both synovial effusion and peri-synovial infiltration mechanically hinder free joint-movement.

Changes in form.—Changes in form are due to

the alterations in shape and texture of the joint-structures, and to effusions within its cavity. These changes may be best appreciated by careful measurements, and a comparison with the opposite joint. The practitioner is thus better able to diagnose the special character of the swelling, whether it be due to synovial effusion, and confined to the limits of the capsule, causing it to bulge at the least protected parts; or to chronic thickening of the synovial membrane, recognised on palpation by its elasticity and more general diffusion; or to disease of the bone and periosteum, when the swelling is deep-seated and hard. By accurate comparison a fluid collection outside the joint, either an abscess or a bursal tumour, may be distinguished from intra-articular swelling.

Pain.—The character of the pain is an important symptom in diseases of the joints. In acute synovitis it is severe and lancinating. In bone-inflammation it is a dull aching pain, with marked local tenderness, liable to periodic exacerbations of an intense kind. Often the pain is of a shooting, starting character, wakening the sufferer from sleep. The pain is of this character and most severe in sub-articular osteitis. Pyæmic suppuration and chronic synovitis are generally painless.

Physical signs.—When one hand is laid flat upon a diseased joint while the other moves it, certain sensations or sounds are often distinguishable. A peculiar soft crepitation, due to the presence of blood-clot, must not be mistaken for the rougher sensations which adhesions afford, the friction-sounds of movable bodies within the joint, or the grating of exposed bone. The rubbing of one granulating-surface upon another may be likened to that of two pieces of velvet. Abnormal movements, such as lateral motion in a ginglymoid joint, usually imply extensive joint-disorder. Displacement or partial dislocation, and alteration in form of the joint-surfaces, occur as the disease progresses. A notable increase of local heat may be felt in all inflamed joints. When fistulous tracks exist around a diseased joint, they do not often, on being probed, afford direct evidence of the condition of the joint, but they generally prove the existence of articular suppuration, and disease of the bone.

COMPLICATIONS AND SEQUELÆ.—The complications which occur in joint-disease are generally connected with long-continued suppuration. Amyloid degeneration of the viscera is pretty certain to be present when suppuration has existed for a year or more in young people; less certainly in adults. Hætic fever, tuberculosis, or pyæmia may occur at any period. In the absence or failure of treatment, the patient, should he survive, will suffer from contraction, deformity, and imperfect growth of the limb, together with more or less complete loss of function.

PROGNOSIS.—The prognosis in diseases of the joints will depend on many circumstances, and must be considered both as regards life and as regards function. First, with respect to *life*, the gravity of joint-diseases increases with the size of the joint affected. They are more serious in the lower than in the upper limb. Pyæmia is comparatively rare in acute joint-suppurations—why, it is impossible to say. When pus escapes from the interior of a joint into the surrounding tissues, pyæmia may occur. A continuous high temperature, or a large evening increase associated with hectic, is a bad sign; the exhaustion, which depends on profuse

suppuration with its attendant hectic fever, amyloid degeneration, and tuberculosis, are the most frequent causes of death in joint-disease. The prognosis as regards *function* is often difficult to determine. After an attack of simple acute or sub-acute serous synovitis, recovery is generally complete. Joint-function is usually absolutely lost after suppuration of traumatic origin, recovery being quite exceptional. When the suppuration is of a pyæmic nature and the patient survives, the effusion may become absorbed, and the joint-motion be preserved or ankylosis ensue. Chronic synovitis with thickening of the sub-synovial tissue, due to infiltration with granulation-material, can seldom be cured except by operation, especially after suppuration has taken place. If recovery should take place, the joint-function is lost, and deformity is always present. Increased mobility—‘flail’ joint—is a very rare sequel of joint-disease. It is occasionally seen in the shoulder, and in the knee.

TREATMENT.—The treatment of diseases of the joints must be directed to preserve the functions of the limb. Of the first and greatest importance among remedial measures is *rest*, which is best secured by fixation of the joint and limb in an appropriate apparatus. This is of cardinal importance to a diseased articulation, just as motion is a necessity for a healthy one. Immobilisation should not be continued longer than necessary; it will sometimes seriously damage even a previously healthy joint, immobilised for instance on account of fracture of the limb; and a continuance of rest after all diseased action has subsided often exerts a prejudicial influence. Rest, however, should be continued so long as swelling, pain, and increased temperature persist.

Position.—The means adopted to secure immobility must be also utilised to obtain the best available position for the future function of the part, should ankylosis become inevitable. In the ankle the foot should be maintained at a right angle; the hip and knee must be kept extended in the axis of the body; the elbow is generally flexed to a right angle, the position in which the limb is most useful. Splints of various forms are used, and we possess in plaster-of-Paris and starch ready and invaluable means of producing an apparatus which gives uniform and equable support of a simple and very perfect kind.

Extension exerts a beneficial influence, as well by immobilising the joint as by its power to remove contraction and deformity. It relieves pain and abates the symptoms rather by keeping the joint at rest, and changing the surfaces of contact, than by any actual separation of the joint-surfaces. A much greater weight than a patient could tolerate would have to be used before any such separation could occur. Extension often even increases the intra-articular pressure. By straightening the limb it removes the joint from its position of maximum relaxation, and puts the skin and tendons on the flexor aspect on the stretch, and alters the mutual accommodation of the joint-surfaces.

As there is almost invariably an increase of temperature in the affected joint, the application of *cold*, by means of ice-bags or coils of cold-water tubing, is indicated. Cold acts most beneficially in all acute, and many subacute inflammations. Even in deep-seated joints like the hip, it will often soothe the pain and abate the symptoms, but it is more applicable to the superficial joints. Cold is

both anæsthetic and prophylactic in its action. The sensations of the patient in respect of the continuance of cold applications must be consulted. In most cases they are grateful. In chronic joint-affections when an acute attack supervenes, threatening suppurative, cold should also be applied. Cold applications may in some cases be continued for weeks or months with advantage. When the acute symptoms have passed off, and it is desirable to encourage lymphatic activity and absorption, the cold must be discontinued, and compression, together with friction and warmth, substituted. Cold is not applicable to purely chronic cases without much pain or tenderness.

In some instances of acute and subacute arthritis *local depletion* by means of leeches or scarification is very useful, and this may be combined with hot *fomentations* in cases where cold is not well borne. In chronic inflammation of the bone the *actual cautery* sometimes procures immediate abatement of the pain, and, after a time, the subsidence of the inflammation. The 'button' cautery may be used, or, still better, linear cauterisation, over the most sensitive points. Or an *issue* may be employed instead.

Compression by strapping, or with a thick layer of cotton-wool and a tightly applied bandage over it, is applicable to the chronic stages of joint-disease. It must be discontinued if it occasion pain. It is better calculated to remove fluid effusions than the plastic material poured out into the peri-synovial tissue. For these cases the more continuous compression of a properly applied elastic bandage will prove more efficient; or the strapping known as 'Scott's dressing.'

Massage is a most valuable local means for the dispersion of chronic swellings of joints. It both removes the results of diseased action in the joint, and helps to restore its function. It is well suited to disperse serous effusions when the acute stage is over; for cases of plastic synovitis it is also useful, but not for cases of the type known as *tumor albus*. It produces a diminution of the sensibility of the part, and a local increase of temperature, and the lymphatics are stimulated to increased activity. There are several modes of employing massage. The first is centripetal stroking with the palm of the hand from the periphery of the affected part towards the centre of the body, called *effleurage*, one hand following the other in immediate succession. The amount of pressure varies with the circumstances of the case. This will readily disperse fluid effusions both of blood and serum. Friction-massage is another useful method, and is practised by pressing the palm firmly upon the surface, and then rotating it. This plan may be combined alternately with the last method, massage proper—*pétrissage*—which is done by raising up the soft parts vertically from the bone with both hands, and compressing them, always in a centripetal direction. See MESSAGE.

Forcible movements.—Forcible movements, which break down adhesions, are often most useful in cases of stiff joint arising after protracted immobilisation, as after fracture in the vicinity of a joint, or after a severe sprain. Pain will be relieved in this way, and mobility restored in some instances, in a degree quite remarkable. They are less applicable in cases of fibrous ankylosis.

Constitutional treatment.—Where any general taint exists, this must be dealt with at the same

time. A tendency to tuberculosis must be met by iron, tonics, good food, and pure air. Gout, syphilis, or rheumatism must, when present as a diathesis, be appropriately treated.

Operative treatment.—Puncture alone, or combined with antiseptic washing-out of the articulation, may often be performed with advantage, to evacuate the fluid in a distended joint, or to diagnose the presence of pus and evacuate it when suppurative has taken place. Sufficiently free incisions, however, and the insertion of drainage-tubes, are generally to be preferred in cases of joint-suppurative; and with these should be combined the washing-out the joint-cavity with a three- or five-per-cent. solution of carbolic acid, or other effective antiseptic. It has been proposed to substitute free incisions and drainage for excision of the joint, in certain chronic forms of disease, such as white-swellings, but excision, or arthrectomy, is probably in most respects preferable. Excision is practised for chronic joint-disease not amenable to other means; it is not a substitute for amputation, but is intended to obviate its necessity. Subperiosteal resection, where practicable, possesses many advantages, especially in cases of traumatic origin. The attachments of the muscles and tendons, and the cellular interspaces between them, are thus left undisturbed. The chances of peri-synovial suppurative are diminished, and the bleeding is reduced to a minimum. There is more complete bony reproduction of the joint-surfaces, and in young persons a new joint very similar to the normal is in some instances formed, while in all cases there is a probability of better subsequent function and position. The operation thus performed requires time and skill. It is scarcely applicable to the knee or even the hip, and is unsuited for cases of chronic synovial disease, where it is of the last importance to excise all the diseased granulation-material. The after-treatment of excisions is of great importance. Plaster-of-Paris bandages supply one of the most useful means of immobilisation, especially in those cases where ankylosis is sought for, as in the knee; and the splint should be unchanged, if possible, for four or five weeks. In the elbow, shoulder, and wrist, where mobility is the end aimed at, passive movement should be commenced as soon as the condition of the wound admits of it—namely, in about a week or ten days. Galvanism must be used at a later period to restore the wasted muscular apparatus. Arthrectomy aims at the removal of all the diseased tissue, yet stops short of a formal excision in which healthy parts may be removed.

Amputation is only performed as a last resort. It is very rarely needed for joint-diseases in the upper limb, except perhaps the wrist, when the hand is permanently crippled. In the lower limb, amputation must be performed in those cases in which the patient has lost all strength and healing power, from the drain of a long-continued discharge. It is advisable where amyloid degeneration or incipient tuberculosis exists, or in any case, in short, in which the power of the patient is inadequate to furnish the amount of repair required in the expectant form of treatment, or in case of excision, always a more serious operation than mere amputation. Amputation should also be adopted in those cases in which the local disease, especially of the bone, is too extensive to admit of a good functional result after excision. In the very young

formal excision is undesirable, since the epiphyses are almost of necessity sacrificed, and the growth of the limb checked. Resection in some joints is practised to avert ankylosis, or to restore the lost function of the joint, as in the shoulder, elbow, and wrist. Various congenital and other deformities of the joints may be removed by osteotomy of the bones concerned.

1. Joints, Cartilages of, Diseases of.—See CARTILAGE, Diseases of; BONE, Diseases of; and following sections.

2. Joints, Congenital Dislocation of.—DESCRIPTION.—This is a curious and ill-understood affection of the joints. It is almost exclusively confined to the female sex. The hip-joint is nearly always the one affected, and the displacement is generally double. It has often been erroneously mistaken for morbus coxae, and treated accordingly.

It probably occurs in early foetal life from defective formation of the joint-surfaces. It is not discovered until the child begins to walk, which it generally only commences to do at a late period. When the hips are the joints affected, the gait is accompanied by a most ungainly swaying of the body from side to side like the waddling of a duck. Great improvement may be effected if the dislocation be reduced and the head of the bone kept in the socket by fixing the limb and pelvis with plaster in a suitable position.

3. Joints, Immobility of.—SYNON.: Ankylosis; Fr. *Ankylose*; Gr. *Gelenkverwachsung*.

ÆTIOLOGY.—This condition may be due to changes in the structures of the articulation constituting a *true ankylosis*; or in those surrounding the joint, a *false ankylosis*. It may be fibrous and incomplete, or bony and complete. False or spurious ankylosis—extra-articular—may depend on muscular spasm or rigidity; on cicatricial contractions; on paralytic or spasmodic affections; or upon prolonged disuse of the joint. It is often difficult, even under chloroform, to distinguish the presence of absolute bony ankylosis, as the fibrous form may be so strong and extensive as almost wholly to prevent movement. The two varieties are but degrees of the same process. Both may result from previous inflammatory changes in the joint, either of the nature of plastic synovitis, or of granulations springing from the bone and other joint-tissues, becoming further organised. Fibro-cartilaginous ankylosis is a common form in young persons. In time it usually becomes converted into true bony ankylosis.

The marked ankylosis which tonic spasm and rigidity of the muscles produce in the early stages of some joint-diseases, as in the hip-joint and knee, may be called *vital* or *physiological*. It is induced by an effort to avert pain; it disappears entirely during necrosis. A joint may become stiff and ankylosed by long fixation on account of some injury or disease elsewhere, especially if it be retained in a flexed position, as the muscles of the flexor side actually shorten when their points of origin and insertion permanently approach one another. The same thing may also happen in the muscular atrophy due to paralysis; in which the cartilages and bones atrophy at the same time.

TREATMENT.—The treatment of diseases of joints should, in all cases where it is possible, be prophylactic against the occurrence of ankylosis. When this has taken place in an incomplete degree, an attempt to restore the function of the limb must

be made, by breaking down the adhesions by forcible or gradual extension, by passive motion, by massage, and by tenotomy of the tense tendons. Excision is indicated to restore motion in complete ankylosis of such joints as the wrist, the elbow, and the shoulder. In other cases of complete ankylosis, especially in the lower limb, surgical interference should be confined to an attempt to rectify a faulty position either by tenotomy, extension, forcible straightening, excision, or osteotomy. Amputation can only be needed in extreme and otherwise irremediable deformity.

4. Joints, Acute Inflammation of the Synovial Membrane of.—SYNON.: Acute Synovitis; Fr. *Synovite Aiguë*; Ger. *Acute Synovitis*.

This is one of the most common of all joint-affections. Probably in half the total number of chronic joint-diseases the synovial membrane is first affected. The synovial membrane is very rich in vessels and cells; and much exposed to injury, and to the effects of movement. An inflammation beginning at one point soon spreads over the whole synovial sac.

DESCRIPTION.—Acute synovitis is a very common result of injury. It also occurs in rheumatism, gout, pyæmia, and other diseases. It may be serous, sero-fibrinous, or purulent. Serous synovitis is the simplest and most common variety. Even a slight external injury is often sufficient to produce it; a sprain of the joint, or excessive movement, may cause it, as well as the constitutional disorders already mentioned. The knee is very often affected, from its exposed position, and the large area of the serous membrane lining it. The synovial membrane becomes injected and thickened, with effusion into the sub-synovial tissue. The natural secretion is increased in quantity, and many cells are shed into the joint-cavity, the capsule becoming swollen, tense, fluctuating, or elastic. The least protected parts bulge, from the pressure of the effused fluid, and the normal contour of the joint is lost. It is usually semiflexed. A severe, burning, cutting pain is experienced in it. It is exceedingly sensitive to pressure, and painful on the slightest movement. There is usually considerable fever. When the inflammation is more intense, the synovitis becomes sero-fibrinous. Flakes of lymph are mingled with the synovia; layers of false membrane cover the synovial membrane, which is considerably thickened and dull-red in colour; and the constitutional disturbance is greater. Finally, it is but a short step from this to suppurative synovitis. If the irritant cause continue its action, the leucocytes filling the meshes of the synovial membrane are shed in larger quantity; the fluid becomes turbid and puriform; the fever and local symptoms increase very much in severity; the external parts become implicated in the inflammation within; and suppuration or abscess is the result.

TREATMENT.—The treatment of the first two stages of synovitis is directed primarily to check the progress of the inflammation; and then to procure resolution, and absorption of the effused fluid. Fortunately the synovial membrane possesses very active absorbent powers; and early and efficient treatment, conjoined with removal of the source of irritation, will generally ensure a cure, with complete restoration of function. The chief means are cold applications; immobilisation till

the acute stage is over ; and then compression and friction, or in suitable cases counter-irritation. Gout, rheumatism, or other diathesis, must be appropriately treated at the same time.

In those cases in which the inflammation has persisted for some time, and plastic effusion has taken place on the surface and in the substance of the synovial tissue, the joint will remain for a long time stiff and thickened, and its function impaired, after all acute symptoms have subsided ; while in those cases where the inflammation has continued long enough to invade the other joint-structures, a perfect cure may not be possible.

When suppuration occurs, the joint must be dealt with as any other abscess-cavity. Free incisions must be made into it, and it should be thoroughly washed out with some antiseptic solution, free subsequent drainage being provided for. In the more favourable cases, ankylosis in a convenient position will be obtained. Recovery of function is very rare. In other cases the suppuration continues ; the cartilages become necrosed and detached ; the bone becomes exposed and carious ; and either excision or amputation must be performed to save the patient's limb or life.

5. Joints, Chronic Inflammation of the Synovial Membrane of.—SYNON. : Chronic Synovitis.

Chronic synovitis may arise as the sequel of the acute disease ; or, as is more frequent, it may depend on some constitutional dyscrasia, or at least some continuously acting irritant, although in the first instance it is generally excited by an accidental injury.

VARIETIES.—There are three chief varieties of this disease which are often co-existent, namely : *pannus-synovitis*, *granulation-synovitis*, and *papillomatous synovitis*.

a. *Pannus-Synovitis*.—In this variety a delicate membrane will be found, stretching from the inflamed and thickened synovial margins more or less over the surface of the cartilage, to which it may be in whole or in part adherent. This change may result simply from prolonged rest.

b. *Granulation-Synovitis*.—The condition formerly described under this name is, in the large majority of cases, of tubercular origin. See section 8.

c. *Papillomatous Synovitis*.—SYNON. : Fimbriated disease of the synovial membrane ; Papilloma, or Papillary Fibroma of the synovial membrane ; Ger. *Gelenkscotten*.

This is a peculiar form of joint-disease dependent on chronic synovitis, in which numerous pedunculated bodies, cylindrical or fusiform, varying in size from a pin's head to a large pea, project from the membrane, generally near the margin of the cartilage, or may cover the entire surface. These bodies are identical in minute structure with the synovial fringes. Some become detached, and fall into the cavity of the joint. There may be dozens or hundreds of these bodies present in one joint. Occasionally they contain cartilage-cells, or osseous particles. The joints of the lower limb are most often affected.

TREATMENT.—The disease is scarcely remediable except by arthrectomy or excision of the joint, which may be practised in those cases in which there is serious loss of function.

6. Joints, Gonorrhœal Inflammation of. See GONORRHEAL ARTHRITIS.

7. Joints, Gouty Inflammation of.—See GOUT.

8. Joints, Tubercular Inflammation of.—This is most frequent in the knee- and hip-joints. Almost all the cases described as *tumor albus* are cases of tubercular disease.

ANATOMICAL CHARACTERS.—This disease generally commences in the synovial membrane, which becomes thickened, and by degrees converted into a semi-gelatinous mass of granulation-tissue, yellowish-white or pink in colour. Or the disease may originate in osteomyelitis of the end of the bone, the inflammatory process being essentially chronic and dependent upon the presence in the tissues of miliary tubercle. After the disease has existed for some time, it is difficult to determine in what tissue it may have originated, and it is of little clinical importance to do so, for in any case the later stages of the malady present similar features. The cartilages are encroached upon from their margins and from their deep surfaces by the granulations, springing from the synovial membrane and the articular lamella, while active changes occur simultaneously in their substance, similar to those already described. The ligaments soften, and all the structures of the joint become involved. Frequently larger or smaller masses of necrosed bone will be found in the cancellated structure, and the granulations have a great tendency to suppurate. In the thickened synovial membrane, and also in the ends of the bones, miliary bodies, identical with tubercles, may very frequently be detected.

SYMPTOMS.—In tubercular inflammation of the synovial membrane the joint is uniformly swollen, tense, elastic, with a white glistening surface, and enlarged veins shining through the skin. The patient can usually move about until suppuration has taken place, as the pain is never very severe in the intervals of the acute attacks of inflammation which supervene from time to time. Enlargement of the lymphatic glands, or marks of strumous ulceration elsewhere, are seldom wanting ; while sooner or later a large proportion of the individuals affected by this form of joint-disease show signs of general tuberculosis. Sometimes this state precedes, but generally it follows, the local joint-affection. When the disease begins in the bone the localised tenderness and deep-seated thickening, conjoined with the general symptoms, may reveal the nature of the process before the more general invasion of all the joint-elements.

TREATMENT.—This must be mainly directed to improving the patient's general condition. Any local treatment, short of a complete removal of the diseased structures, is not of the least use when the joint has become disorganised, as before described ; and some form of excision should be performed before the viscera become implicated. If other organs be involved, or the local disease be too extensive, then amputation becomes imperative. When not removed, fresh foci of suppuration form ; the patient becomes more and more exhausted ; or some intercurrent disease sets in. It is rare for spontaneous cure to happen.

9. Joints, Loose Cartilages in.—SYNON. : Fr. *Corps Flottants Articulaires* ; Ger. *Gelenkmäuse*.

DESCRIPTION.—'Loose cartilages' in joints may originate either from chronic inflammation or from traumatic causes. They may be single or multiple. The knee-joint is most frequently affected, and in it

the most serious symptoms are produced. These bodies may be fibrous, fatty, cartilaginous, or partly ossified. They may be produced from polypoid growths springing from the synovial membrane in certain forms of chronic synovitis, and in arthritis deformans; and they are then usually of the fibrous or osteoid variety. Free bodies consisting of fat are rare, and are derived from the subsynovial fatty tissue, often produced in a fashion analogous to the appendices epiploicæ of the great intestine.

The cartilaginous and osteoid formations are the largest and most important varieties of these bodies; hence the common term 'loose cartilage.' Portions of the joint-surface may sometimes become detached, as the consequence of injury, or by a process of quiet necrosis. They thus become loose in the joint. It is stated, but the fact is doubtful, that some of these bodies may obtain nourishment from the surrounding synovial fluid, and that cartilage and even bone can be developed in them subsequently to their detachment.

SYMPTOMS AND DIAGNOSIS.—The symptoms of loose cartilages in a joint vary very much. In some instances these bodies cause no inconvenience. In others they produce repeated attacks of excruciating pain, followed by synovitis, laying the patient up for weeks; while in the most severe cases the limb may become almost useless. When the knee is the joint affected, the patient experiences great insecurity in walking, the loose body from time to time becoming wedged between the joint-surfaces. The joint is thus 'locked.' The patient may suddenly fall, or faint with pain; an attack of synovitis follows; and with a frequent repetition of this process joint-disorganisation may finally result. The prognosis as regards function is always bad.

TREATMENT.—The treatment of loose cartilages may be either *palliative* or *radical*.

The *palliative* method consists in applying support to the joint; limiting its movements; and fixing the loose body in some synovial pouch where it cannot interfere with the articular surfaces.

The *radical* method consists in excising the body—an operation, with few exceptions, almost exclusively practised upon the knee-joint. The body may be removed by a free direct incision into the joint, and squeezing the body through the wound at once. Or the indirect manner of operating may be adopted. This consists in subcutaneously incising the capsule of the joint with a long narrow-bladed knife introduced at some distance from the articulation; forcing the body through this incision into the cellular tissue outside; and then closing the small external puncture in the skin. Three or four weeks later the 'cartilage' may be removed by a superficial incision, or left undisturbed, when it often becomes absorbed.

In appreciating the comparative value of these two plans, it may be said that the former has hitherto proved more uniformly successful *quoad* extracting the body, but that it has been more dangerous to limb and life—a danger, however, which antiseptic precautions reduce to a minimum. The indirect method has been attended by a considerable number of failures in the extraction of the loose cartilage, especially if it be pedunculated; but it has hitherto proved a less dangerous operation. The extremity should be immobilised afterwards for two or three weeks.

When some dozens of these bodies are present in a joint, many of them free, many attached, excision

of the articulation is often the only remedy. This is a severe measure, and not to be lightly undertaken, in the joints of the lower limb at all events.

10. Joints. Nervous Affections of.—**SYNON.**: Hysterical Joint; Neuralgia of Joints; Arthralgia; Fr. *Arthralgie Hystérique*; Ger. *Gelenkneurose*.

DESCRIPTION.—*Hysterical affections* present symptoms simulating real joint-disease so closely that the most energetic therapeutic measures have often been resorted to, though in vain, for their cure. Prolonged immobilisation, blistering, the actual cautery, resection, and even amputation, have been practised upon joints in which there was not a trace of organic disease.

The existence of hysterical affections of joints is denied by some; but assuredly they do occur; and most often in young women, well-to-do in life, with disordered catamenia. The same thing occurs, but less frequently, in young men. The disease is not witnessed under the age of puberty. The hip and knee are the joints principally complained of—most frequently the latter. An all-important feature of an hysterical joint is that, while the local symptoms may be intense, the general symptoms are either absent, or in no sort of proportion to the local.

A special character of this disease is that deep pressure is often less painful than superficial pressure; and that the pain and tenderness are vague, shift from one point to another, and will disappear at a given spot when the patient's attention is directed elsewhere. There is pain on movement, but of an indefinite character, and not so limited or localised as in real disease. Nocturnal startings do not occur; the patient may enjoy uninterrupted sleep for hours. There is never a continuous rise of temperature, either general or local; the correlation of the symptoms is not the usual one; the function of the joint is much more interfered with than the other features of disease present would appear to justify. There is an exaggerated fear of examination; and the *facies hysterica* is often well marked. There may be thickening around the joint, and even marked synovial effusion into it; but these conditions are passive in character, and generally due to the treatment employed. The limb is wasted and consequently weak, but never to the same extent as in real joint-disease. Exacerbations occur at the menstrual period. A careful inquiry should be made into the history and antecedents of the case. An examination under chloroform will often afford important evidence; and the patient's symptoms will be improved afterwards by the movements then practised on the joint.

Neuralgic pain in the articulations may arise under different circumstances. It may be the referred pain, unattended by local lesion, which is so frequent in the knee in cases of hip-joint disease. Neuralgic pains in various joints are observed in the preliminary or early stages of chronic myelitis. In the first stage of locomotor ataxy the knee may be affected by severe neuralgia when the disease is low down in the cord; or the shoulders when it is at a higher point. Lastly, so-called neuralgia of a joint may really indicate some obscure lesion, as chronic inflammation of the bones entering into the formation of the articulation.

TREATMENT.—The methodical exercise of an *hysterical joint* is as plainly indicated as rest is imperative in a case of organic disease. The bowels should be regulated, as also the menstrual flow.

Asafetida, iron, and quinine are most important remedies; and healthy mental and moral influences are valuable adjuncts. 'Get up and walk' is a good prescription in many such cases. Very careful and repeated examination should always be made, to exclude any possible form of chronic inflammation, before pronouncing a joint to be hysterical. It must not be forgotten, however, that after slight injuries which produce some inflammatory symptoms, those of hysterical joint may supervene, and persist long after all traces of organic disease have disappeared.

The treatment of *neuralgia* connected with a joint will necessarily vary with its cause. See NEURALGIA.

II. Joints, Chronic Rheumatoid Arthritis of.—SYNON.: Osteo-arthritis; Fr. *Arthrite avec Usure des Cartilages*; *Arthrite Sèche*; Ger. *Alters-abschleifung*.

ETIOLOGY AND PATHOLOGY.—The number of names that have been applied to this disease betrays the obscurity enveloping its pathology. In nature it is, however, essentially a senile degeneration, accompanied by chronic inflammation; and is, in part, perhaps, the result of wear and tear of the joint. It is most common in hard-working people, exposed to the influence of wet and cold, and in the aged. One or many joints may be affected; generally the fingers, the toes, the hip, and the knee. It may be set up by injury, such as a sprain, dislocation, or fracture; or it may arise without known cause. It is difficult to say which of the tissues is primarily at fault, but sooner or later all become involved. The synovial membrane inflames; papillary outgrowths form upon it; the cartilage swells; and the ends of the bones enlarge. After a time the quantity of synovial fluid diminishes; the joint-friction increases; the cartilages are rubbed away at the surfaces of contact; and finally the bone itself, which becomes denser by interstitial deposit, disappears. The surface is eburnated, and marked with striæ produced by friction; while deposits of new bone, which may often be felt externally, form around the margins of the joints, so that the area of its surfaces becomes greatly increased.

SYMPTOMS.—The symptoms of chronic rheumatoid arthritis chiefly consist in constant pain, of a dull aching character, and worse at night. Motion becomes more and more difficult and painful as the disease advances; but ankylosis never occurs. Rough crepitus is felt both by the patient and the surgeon when the joint is moved. See RHEUMATOID ARTHRITIS.

TREATMENT.—The treatment of osteo-arthritis can only be palliative. It consists in the use of warm douches and other warm applications, and the administration of iodide of potassium internally. The disease is incurable.

Charcot's Disease.—This is a peculiar form of osteo-arthritis, affecting usually the larger joints, such as the knee, hip, and shoulder, and occurring in connection with *tabes dorsalis* and *syringomyelia*.

In many instances the changes in the joint are similar to those in osteo-arthritis, while in others there is much more rapid and extensive destruction of bone. Besides the destructive changes which occur in the joint, there is often abundant prolifera-

tion and ossification of the cartilage-margins, so that new irregularly formed masses of bone are found, it may be to as great or even a greater extent than in osteo-arthritis.

SYMPTOMS.—The malady occurs as a rule somewhat early in the progress of a case of *tabes*. The onset is rapid, the synovial effusion greater than in osteo-arthritis, and the wasting and wearing away of the cartilage and bones much quicker.

The swelling generally occurs in the affected articulation quite suddenly and without pain; there is usually no pyrexia or local evidence of inflammation, but the joint may be red and oedematous. Most commonly the knee is affected. The general symptoms of inco-ordination may be strongly marked or altogether absent. It is well to carefully look for them in all cases of extensive chronic enlargement of a joint in the adult. See *TABES DORSALIS*.

TREATMENT.—The treatment consists in giving the affected joint rest, and in the employment of suitable remedies to control the progress of the nervous trouble. The prognosis in most cases is very unfavorable.

12. Joints, Serous Effusion into.—SYNON.: *Hydrops Articulii*; *Hydarthrosis*; Fr. *Hydarthrose*; Ger. *Gelenkwassersucht*.

This is a form of chronic serous synovitis, in which there are no obvious inflammatory symptoms. The joint sometimes becomes greatly distended; the ligaments are stretched; and in consequence there is a sensation of tension and feebleness in the articulation. The knee and elbow are most frequently attacked; and the disease is often associated with a gouty or rheumatic diathesis, or with rheumatoid arthritis. It is very difficult to cure. The joint may be punctured and the fluid drawn off; or, still better, it may be injected and thoroughly washed out with iodine (equal parts of the tincture and water), or with a carbolic acid ($2\frac{1}{2}$ to 5 per cent.) solution. Relapses, however, are common.

13. Joints, Syphilitic Disease of.—This disease may originate in children, in the form of a suppurative osteitis at the junction of the epiphysis and diaphysis. Other signs of congenital syphilis will help to establish the diagnosis. The disease runs a rapid course, and the joint is frequently destroyed. In the adult a chronic plastic synovitis, due to gummatous infiltration of the peri-synovial tissue, or of the bone and periosteum, is the more common form. There is very little fluid effusion within the joint, but considerable impairment of mobility is produced by the thickening outside it. The progress of the disease is slow and painless, except at night or on motion. The history of the case; the presence of traces of syphilis elsewhere; and the effects of treatment, will help in establishing the diagnosis. The internal use of mercury and iodide of potassium, combined with local pressure by means of strapping with mercurial plaster, speedily effects a marked improvement and cure.

K

KALA-AZAR (Sans. *Kala*, black or deadly; Assamese (?) *Azar*, sickness).—Kala-Azar, or the black disease of the Garo Hills, is epidemic in Assam and in the country between the Brahmaputra and the Garo Hills. It takes the form of a chronic and relapsing infective fever, causing profound and progressive anæmia, wasting, and dropsy. It usually affects several members of the same household, and has a high mortality.

SYMPTOMS.—Ross divides the various manifestations of the disease into three stages, viz.: (1) that of recurrent attacks of high fever with rapid enlargement of the liver and spleen; (2) that of great enlargement of these organs with constant low fever; and (3) that of 'cachexia.'

1. The early stages cannot be distinguished from ordinary malaria. The fever may be first remittent, and afterwards intermittent. Rigors are frequent or absent. In many cases the fever may cease for long intervals, and then be followed by relapses; in others, the preliminary febrile attacks are followed by slight continuous fever, with occasional exacerbations. The subsequent course of the affection usually follows one of two distinct types: one accompanied by general wasting with enlargement of the spleen and liver, and the other by the same symptoms together with dropsy of the legs and abdomen; the latter is the rarer variety. Anæmia and emaciation set in early, the feet become œdematous, and the skin assumes a leaden hue.

2. During the second stage the enlargement and tenderness of the liver and spleen persist, with constant low fever, relieved by occasional exacerbations. The diurnal temperature-curve remains constant, and the amplitude is not great. The anæmia remains well-marked; emaciation is not always extreme. Ascites is nearly always present, and sometimes dropsy of the feet and face. Epistaxis is common. Towards the end of this stage, if the patient survive, the continued enlargement of the organs ceases, tenderness disappears, and the fever declines.

3. The commencement of this stage marks the point after which recovery is impossible. The fever may become changed into a subnormal temperature. The ascites increases, though the dropsy of the feet lessens. The anæmia is not very extreme. Inter-current affections of the lungs or bowels may end the case, or death may result from asthenia.

DURATION.—According to Rogers the usual duration is from four to nine months, the extremes being two months to three years. Ross puts the first stage at one to two months only, and the beginning of the third stage at nine months or a year from the commencement of the illness.

MORBID ANATOMY.—There is great *wasting* of the extremities, with *ascites* and sometimes *dropsy* of the feet and legs. The *skin* is dark. The chief changes are found in the *liver*, which may be twice its normal size, harder than usual, and showing an excess of interlobular tissue. The *spleen* is also enlarged, averaging 2½ lbs. (21 cases, Rogers). The *supra-renal capsules* are normal. The *yellow marrow* is converted into red, is softer than usual, and free from the normal small spicule of bone. The *heart* is in a state of granular and fatty degene-

ration. The *small intestine* is thinned and pigmented.

ÆTIOLOGY AND PATHOLOGY.—There has been much controversy concerning the causation and nature of this disease, but only two views need be mentioned here. The first is that the disease is a form of ankylostomiasis, the other that it is a manifestation of malarial disease. There is no doubt that the large proportion of patients affected by this disease also suffer from ankylostomiasis; but that this is the causative condition is rendered extremely improbable by the facts that 67 per cent. of the presumably healthy inhabitants in affected districts suffer from ankylostomiasis; that fever is uncommon in the latter disease; that the death-rate is much lower; and that the anæmia differs in the two diseases. In kala-azar the sp. gr. of the blood is but little reduced, there is generally leucopenia (see p. 156), and the colour-index of the red corpuscles is about normal.

The malarial theory of the disease is maintained by Rogers, who believes it to be an exceptionally virulent form, and by Ross, who regards it as ordinary malaria. The disease certainly occurs in malarious districts, and the symptoms and pigmentation are identical with those of malarial fever; but, on the other hand, the death-rate is high; the symptoms are less constant; the disease is probably communicable from the sick to the healthy, and quinine is powerless in its treatment. The disease is endemic in places where the inhabitants suffer largely from both ankylostomiasis and malaria, and it is possible that in kala-azar there is some additional source of infection not yet discovered.

COMMUNICABILITY.—Kala-azar spreads along the lines of traffic. People living in a house in which other cases are present, or visiting friends sick of the disease, are especially liable to contract the disorder, but only if they reside for some time with infected persons. Ross holds that the disease is only communicable by the mosquito as in ordinary malaria.

TREATMENT.—In consequence of the large number of cases in which ankylostomiasis exists the dejecta of all patients in localities where ankylostomata are present should be examined for the ova of these worms as a routine duty (see ENTOZOA). If the parasites of malaria are present give quinine in large doses, but when they have disappeared, only small doses, the patient now requiring tonics, and nourishing food, especially milk. These small doses of quinine should be given for weeks or months continuously after an attack of malarial fever.

If the spleen is much enlarged the continued use of quinine and sulphate of sodium is indicated.

Preventive Measures.—Bearing in mind that the disease is probably a communicable one, Rogers recommended: (1) that all newly imported coolies should be placed in fresh huts, and not allowed to enter old infected ones. (2) In slightly infected huts all infected persons, together with their households, should be moved out into separate segregation-lines, and the huts which they had inhabited should be burnt and not rebuilt. (3) In badly infected lines all the healthy people should be moved out during the dry cold weather, when infection is at a

minimum, and placed in new lines, while the infected persons and their households should be segregated, and the infected lines abandoned.

As far as tea-gardens are concerned, this practice has been attended with success. Thus in a certain tea-garden in which 200 coolies were lost in the course of four years from the disease, new huts, a quarter of a mile from the old ones, were built, the old ones burnt down, and the coolies moved into the new ones. The epidemic ceased. In another case all the new coolies were placed in new huts and no new case occurred, whereas cases arose among the old coolies in the old lines.

ANDREW DUNCAN.

KAPOSI'S DISEASE.—See XERODERMIA PIGMENTOSA.

KATATONIA (κατά, down; τόνος, tension).—See INSANITY (Mental Stupor).

KELOID.—See CHELOID.

KERATINISATION.—The name applied by Unna to the process by which pigmentation occurs in xeroderma and ichthyosis, believed by him to consist of a partial loss of water and oxygen, and a consequent relative increase of sulphur.

KERATITIS (κέρας, a horn, the cornea).—Inflammation of the cornea. See EYE, AND ITS APPENDAGES, Diseases of.

KERATODERMIA.—See TYLOSIS.

KERATO-HYALIN.—The substance, the exact nature of which is unknown, deposited in the cells of the deep Malpighian layer of the skin as they become changed into horny cells. See KERATOSIS.

KERATOSIS.—The process by which the soft cells of the Malpighian layer of the epidermis are converted into horny cells, a process accompanied by the deposition of kerato-hyalin in their interior.

KERION (κηρίον, a honeycomb).—SYNON.: *Tinea Kerion*; *Kerion Celsi*.—A term applied to a pustular folliculitis of a scalp affected with ringworm. The inflamed area occurs in the form of one or several blotches of a deep red colour, prominent, and dotted over with yellow spots—the apertures of the empty hair-follicles, which exude a copious muco-purulent fluid. The yellow spots are converted into tumid hollows of distended follicles by the swelling of the inflamed skin around them. Another feature of the disease is the actual destruction of the hair-follicles, and the subsequent baldness of the affected part. The production of an 'artificial kerion' by the application of croton oil to the scalp is one of the methods of treatment of tinea tonsurans. See TINEA TRICHOPHYTINA.

JOHN HAROLD.

KERNIG'S SIGN.—A temporary rigidity occurring in the flexors of the knee which can be induced in all cases of spinal meningitis by flexing the thigh to a right angle. In this position the leg cannot be fully extended upon the thigh.

KIDNEY, Diseases of the.—The diseases of the kidney will be considered in the following order:—

Abscess, p. 821.

Amyloid Disease, p. 821.

Anomalies, p. 822.

Atrophy, p. 823.

Consecutive Inflammation, p. 823.

Cystic Disease, p. 827.

Embolism, p. 828.

Fatty Disease, p. 829.

Granular Kidney, p. 829.

Hæmorrhage, p. 831.

Hydatid Disease of, p. 831.

Hyperæmia, p. 832.

Hypertrophy, p. 833.

Inflammation of, p. 833.

Inflammation of Pelvis of, p. 834.

Malformations, p. 822.

Malpositions, p. 835.

Morbid Growths, p. 836.

Parasites, p. 838.

Syphilis of, p. 838.

Thrombosis of, p. 838.

Tuberculosis of, p. 838.

The following is a list of articles on cognate subjects which appear in their alphabetical position in other parts of the Dictionary:—ACTINOMYCOSIS; ALBUMINURIA; ALBUMOSURIA; BRIGHT'S DISEASE; CONCRETIONS; CHYLURIA; DIABETES MELLITUS; DIURETICS; DROPSY; HÆMATURIA; HÆMOGLOBINURIA; LITHONTRIPTICS; NEPHRALGIA; OXALIC-ACID DIATHESIS; PAIN IN VISCERAL DISEASE; PERINEPHRITIS; PHOSPHATURIA; POLYURIA; RENAL CALCULUS; URÆMIA; URINARY DEPOSITS; URINE, Morbid Conditions of.

GENERAL CONSIDERATIONS.—The effects produced by renal disease may generally be classified under three heads: (1) the local effects produced in the kidney itself; (2) the changes produced in the composition of the urine; and (3) certain remote effects produced on the body at large.

1. *The local effects*, such as the production of a tumour or the development of cysts, or the presence of one or more of the varieties of renal pain, will be discussed under the headings of the individual diseases.

2. *Changes in the Urine.*—The urinary changes produced by renal diseases will be discussed in the article URINE, Morbid Conditions of.

3. *Effects produced by Renal Disease on the Body generally.*—These may be classified as follows:

(1) *Nutritional.*—The nutrition of the body generally suffers in renal disease, partly owing to the interference with digestion and absorption, but apparently also indirectly owing to an action of the renal tissue on the metabolism of the body generally, inasmuch as the experimental removal of a large amount of the renal tissue is followed by a condition of extreme wasting accompanied by the excretion of a copious urine containing an increased quantity of urea. In renal disease wasting is often a prominent feature, quite out of proportion to any gastric disturbance, nausea, vomiting, or diarrhoea produced by the malady. In granular kidney and other destructive diseases of the renal substance wasting is a prominent feature. Further the temperature of the body is often subnormal in renal disease.

(2) *Resisting power.*—The resistance of the tissues to microbic infection in renal disease is undoubtedly diminished, and this is one of the reasons why such patients are so liable to secondary inflammations. The most common secondary infections in renal diseases are pericarditis, pleurisy, peritonitis, and pneumonia.

(3) *Dropsy*.—Dropsy is a prominent feature in some forms of renal disease, but is not present in all, being more especially characteristic of Bright's disease in its acute form and in one form of chronic Bright's disease, the so-called large white kidney. It is less frequently seen in the granular kidney, the contracted white kidney, and cystic kidney. Patients with renal disease may suffer not only from renal dropsy but also from cardiac dropsy owing to the development of secondary cardiac complications. Dropsy in renal disease is invariably accompanied by a diminution in the quantity of urine excreted; but this is not its cause, as is shown by the fact that complete suppression may occur in a number of renal diseases without the development of dropsy. Therefore it is quite possible that, even in acute Bright's disease and chronic Bright's disease where dropsy is such a prominent feature, this symptom does not owe its origin to the mere diminution in the quantity of urine excreted. It is more probable that the scanty excretion of urine is the result of the dropsy than its cause. Renal dropsy is characterised by involving the subcutaneous tissues, especially the scrotum, the sacrum, and the subcutaneous tissues of the face. Where it is large in amount there is also dropsy in the serous cavities and even the solid organs, more especially the lungs and the brain. The dropsical fluid in renal disease contains only a small amount of proteid matter, often not more than 1 per cent., but large quantities of nitrogenous extractives, especially urea.

(4) *Cardio-vascular lesions*.—In many renal diseases the heart, especially the left ventricle, undergoes hypertrophy, and the arteries, not only of the kidney but of the body generally, are thickened by changes in all their coats. The sub-endothelial coat presents the most characteristic changes, owing to a very great increase in the amount of elastic tissue and the development of loose fibrous tissue between the elastic laminae. It is not unusual for the inner coat to equal in thickness the middle and the outer. The thickening of the inner coat is not uniform, and frequently involves only one portion of the circumference of a vessel. The larger arteries have their adventitia increased in amount, and the medium-sized arteries, in addition to presenting the changes described above, may have a well-marked increase in their muscular coat. The changes in the inner coat are often most marked in the vessels of the kidney itself, but considerable variations are found in the degree of the degeneration in the renal vessels and in those of the body generally. These arterial lesions are limited to cases of chronic renal disease, and are best marked in chronic Bright's disease and in the granular kidney.

The degree of development of cardiac hypertrophy and of the arterial lesions is not entirely dependent on the diminution in size of the kidney, as extreme forms of contracted white kidney and even of the granular kidney are seen where the cardiac hypertrophy is small in amount and the arterial lesions less developed than in other cases where the renal lesion is less marked.

Speaking generally the arterial lesions are such as may be correlated with the high pressure. Some pathologists have thought that the arterial lesions are primary and that the cardiac hypertrophy is induced secondarily to them, others that the cardiac hypertrophy is primary and that the arterial lesions are such as would be produced as a result of the

increased arterial pressure. Arterial lesions may often be detected on ophthalmoscopic examination by the undue rigidity and thickness of the retinal arteries. These arterial lesions are not seen usually in such destructive diseases as cystic kidney and hydronephrosis, notwithstanding that the quantity of renal tissue is greatly diminished. This affords a further reason for thinking that their production is not entirely dependent on mere destruction of renal tissue.

(5) *Uræmia* is the name given to the toxic state liable to supervene in almost all forms of destructive renal disease, and is considered elsewhere. See URÆMIA.

KIDNEY, Abscess of.—Suppuration in the substance of the kidney may exist in the form of a number of diffused abscesses of small size, or as a single abscess of larger size. The former condition is most usually seen in so-called 'surgical' kidney (see KIDNEY, Consecutive Inflammation of), the latter as the result of infective embolism. Infective embolism may, however, give rise to multiple abscesses of small size as in malignant endocarditis. Where a single abscess is present without known cause, it is generally the result of infection from some other part of the body. An abscess in the kidney may either rupture into the pelvis and so be spontaneously evacuated, or it may perforate the capsule and form a perinephric abscess. See PERINEPHRITIS.

Renal abscess may be suspected and diagnosed if, some days after the occurrence of a rigor and renal pain, a considerable quantity of pus suddenly appears in the urine. Cases of single abscess of the kidney which rupture into the renal pelvis frequently recover completely. Where the abscesses are multiple the prognosis is more serious owing to the underlying condition.

KIDNEY, Amyloid Disease of.—**ÆTIOLOGY AND MORBID ANATOMY.**—See AMYLOID DISEASE.

SYMPTOMS.—The onset of the disease is gradual, and frequently the first manifestation of the disorder is the passage of an increased quantity of urine. The urine is of low specific gravity, and it is stated that at the actual onset of the disease it is free from albumen. Soon, however, albumen is present in variable amount, but usually where the quantity of urine is greatly increased the percentage amount of albumen is small, although greater than that seen in the granular kidney. One hundred ounces of urine may be secreted in the twenty-four hours, and cases have been described where two hundred ounces have been passed. In such cases the quantity of urea secreted in the twenty-four hours is not markedly diminished; the urine contains but few casts, and these are usually hyaline. In another form of the disease the clinical picture is quite different; dropsy is a marked feature, often resembling in its distribution the cardiac form of dropsy more closely than that seen in Bright's disease. Cases of amyloid disease, however, may be seen where the general subcutaneous dropsy is marked in amount and very similar in distribution to that of Bright's disease. In such cases the quantity of urine is diminished, and, although its specific gravity may still remain low and its colour pale, such urine may contain large quantities of albumen. All gradations are seen between cases where a copious urine containing but a trace of

albumen is secreted and those in which the amount of urine is small but loaded with albumen. In the latter form of the disease granular and hyaline casts are more abundant, and in some instances casts giving the amyloid reaction with iodine have been detected. The duration of both forms of the disease is uncertain, as it is so largely dependent on the course of the original malady producing it, but the latter variety may last for as long as two years, and the more chronic for six. The other symptoms produced may be largely masked by those dependent on the original malady, but anæmia and wasting are usually marked features, and uræmia is by no means uncommon as a fatal complication. The fatal issue is more dependent on the original disease than on the amyloid degeneration of the kidneys produced by it. In some instances changes in the fundus oculi similar to those seen in chronic Bright's disease occur.

DIAGNOSIS.—The condition often resembles one of the various forms of Bright's disease. The existence either of polyuria with slight albuminuria, or of scanty urine with marked albuminuria and dropsy, without any signs of cardiac enlargement or arterial thickening or degeneration, is most suggestive of amyloid disease, especially if the spleen and the liver be enlarged. In cases of pyelitis the existence of marked albuminuria out of proportion to the amount of pus in the urine is very suggestive of the existence of this complication. It is important to recognise the presence of amyloid degeneration in cases of pyelitis, as the existence of this renal complication may materially influence the prognosis and the results of any operative interference for the relief of the pyelitis. It is not uncommon for fatal uræmia to occur as a result of surgical exploration when the kidneys are affected with amyloid disease as a complication of pyelitis.

The prognosis depends very largely on that of the disease causing this complication. In some instances the successful treatment of the underlying malady is followed by the disappearance of the amyloid disease, and in nearly every case by its arrest.

TREATMENT.—The treatment is similar in most respects to that of Bright's disease, except that, unless complications such as uræmia or dropsy are present, the disease requires a more liberal diet than that ordered in Bright's disease, as it is essential, owing to the existence of a debilitating malady such as suppuration or bone-disease, that a nourishing diet should be given. Further, the amyloid disease, unless very far advanced, is not one which greatly interferes with the excretory powers of the kidney, and there is not therefore the reason for diminishing the nitrogenous ingesta as is so often necessary in other renal diseases. *See* AMYLOID DISEASE.

KIDNEY, Anomalies of.—Kidneys may present three kinds of anomaly: in number, in form, or in position, although two or more of these are frequently combined. *See* KIDNEYS, Malpositions of.

Anomalies in Number.—Both kidneys may be absent during foetal life, but as this condition is incompatible with the maintenance of life, it is only of developmental interest. One or more supernumerary kidneys may be present, but this anomaly is very rare. One kidney only may be present. This may depend on the fusion of two originally

distinct organs, or on the absence or atrophy of the second. If one organ is congenitally absent, no traces of the renal vessels or of the ureter are found on that side; but if it has undergone atrophy during foetal or early extra-uterine life, a remnant of varying size is always present. In the congenital cases the atrophied kidney is frequently found to have been developed in an anomalous manner, so that the glomeruli or the convoluted tubules may be absent. When the atrophy has resulted from pathological changes occurring after birth, the renal artery may be found occluded or the ureter obstructed; and the atrophied kidney will contain remains of altered convoluted tubules and glomeruli, together with a large amount of fibrous tissue. Where the atrophy is of congenital origin, the single kidney that is present is often considerably above the weight of two normal kidneys. In some cases these single kidneys may weigh as much as a pound. The presence of a single large kidney is of no great clinical importance, except that it materially increases the gravity of certain renal diseases such as calculus; such kidneys are, moreover, not uncommonly affected by Bright's disease. In some instances the existence of a single large normal kidney in a patient complaining of abdominal symptoms has been erroneously diagnosed as a renal tumour.

A single kidney resulting from the fusion of two primary separate organs will be considered under anomalies in form.

Anomalies of the renal vessels, especially of the arteries, are very common, and are of some importance to the surgeon. They may lead to the production of hydronephrosis, by causing obstruction to the ureter. Anomalies of the ureter may also lead to the production of hydronephrosis. *See* HYDRONEPHROSIS.

Anomalies in Form.—The commonest malformation of the kidney is for the *lobulation*, which is so characteristic of the foetal kidney, to be more marked in the adult than usual. In cases in which the lobulation is extremely well marked the organ is often malformed in other ways, so as to be considerably longer than normal. It is not uncommon for one extremity of the kidney, especially the lower, to show marked lobulation, and in some instances a portion of the lower extremity may be partially separated from the remaining kidney substance. The *horse-shoe kidney* is also not uncommonly met with. In this condition the two kidneys are united by a bridge of renal tissue, usually joining their two lower extremities. The kidney generally is ill-shapen, and lobulation is well marked. In cases of horse-shoe kidney the arrangement of vessels is anomalous, a number of arteries entering the concave margin of the kidney and also the anterior surface. The ureters usually pass down over the front of the kidney. In some instances the horse-shoe kidney is really spurious, the bond of union being composed of fibrous tissue.

Other instances of malformation of the kidney are afforded by the union of the two kidneys end to end, producing the so-called 'sigmoid kidney.' In very rare instances the two kidneys are fused by their surfaces, forming what has been called the 'disc-shaped kidney.' In both these rare malformations the two ureters are found on one side of the body, but they are distinguished from the condition of double ureter by the fact that one crosses to the opposite side, and they both open in the normal positions in the bladder.

Malformations of the ureter and renal pelvis are not uncommon. A double ureter may sometimes exist, but more often an apparently double ureter is really the result of the non-union of two of the calices. The pelvis of the kidney may be uncommonly large and join a normal or unnaturally small ureter. Cases are sometimes seen in which the ureters and the pelvis of the kidney are dilated and the kidney-substance itself malformed, the appearances being such as to resemble those of hydronephrosis. Some such instances are dependent on congenital obstructions in the lower part of the urinary tract and even on phimosis, but instances occur where no cause for the dilatation of the pelvis and ureters can be found.

Malformations are of no great clinical importance except in so far that certain of them predispose to disease, e.g. anomalies of the pelvis and ureters to hydronephrosis, and dilatation of the ureter to pyelo-nephritis. The presence of such anomalies as a horse-shoe kidney or single fused kidney may lead to errors of diagnosis, from the detection of a mass which is erroneously interpreted as a new formation. Further, in rare instances, a horse-shoe kidney has exerted sufficient pressure on the vena cava to cause thrombosis of this vessel.

KIDNEY, Atrophy of.—This term is best restricted to a condition where the diminution in the size of the kidney is the only morbid process. The extreme forms of atrophy of the kidney involve only one organ. In such cases the kidney may still retain its normal shape, but may not be more than half an inch in its longest diameter. All intermediate sizes between this and the normal may be found.

At least three forms of atrophy may, therefore, be recognised: (1) of developmental origin; (2) from arterial occlusion; (3) from obstruction of the ureter. The atrophy is often of congenital origin, and associated with some anomaly in development (*see above*). The renal artery in some cases is exceedingly narrow, either throughout its whole course or at one spot only, and atrophy thus seems to result from diminution in its calibre. Obstruction of the ureter will also account for some cases, as there is experimental evidence to show that if the hydronephrosis produced by obstruction of the ureter be drained, a very perfect form of atrophy of the kidney results.

The tubules in cases of atrophy of the kidney frequently contain epithelium, which has undergone hyaline degeneration, and is of glass-like appearance. A similar change in the epithelium is seen when the atrophy is produced experimentally by ligation of the ureter.

If the term 'atrophy' be used in its more general sense, atrophy of the kidney is seen in hydronephrosis, in the granular kidney, in the contracted form of Bright's disease, and occasionally even in the amyloid kidney. In all these conditions the diminution in the size of the organ is largely dependent on the contraction and collapse of great numbers of the renal tubules.

Partial atrophy of the kidney is a term applied to the diminution in the size of the organ which follows embolism—the absorption of a necrotic infarct often causing a considerable diminution in the size of the organ accompanied by much scarring.

JOHN ROSE BRADFORD.

KIDNEY, Consecutive Inflammation of.—Under this term are included the various patho-

logical conditions which may affect the kidney as the result of disease or injury of the lower parts of the urinary tract. The very inappropriate name 'Surgical Kidney' is very frequently applied to that form of consecutive inflammation of the kidneys in which scattered foci of suppuration are found in one or both organs.

PATHOLOGY.—Diseases of the lower urinary tract may react upon the kidneys in two important ways: (1) by obstructing the passage of the urine, and so causing abnormal tension in the whole urinary tract above the obstruction, and (2) by the extension of infective processes to the kidneys from the bladder. Further, it is possible that certain phenomena occasionally accompanying affections of the lower parts of the urinary tract may result from reflex disturbances of the renal circulation.

1. Obstruction to the passage of urine may occur in the ureters from congenital malformation, from impaction of a calculus, or from the pressure of a tumour. It may occur at the vesical orifice of the ureter from thickening of the wall of the bladder in hypertrophy, from thickening and induration of the submucous tissue and swelling of the mucous membrane in chronic cystitis, or from the growth of a tumour around the orifice. Obstruction to the passage of urine from the ureters into the bladder also results from any condition in which the bladder is unable completely to empty itself, as in hypertrophy of the prostate and in certain forms of paralysis. Stone in the bladder causes obstruction at the orifices of the ureters by the chronic cystitis to which it gives rise, while stricture of the urethra acts in the same way and by occasioning muscular hypertrophy of the bladder-wall.

In the large majority of cases, whatever be the exact nature of the obstruction, the valvular orifices of the ureters do not become incompetent, and the only force concerned in the dilatation of the ureter and pelvis of the kidney is the force of the renal secretion. Exceptionally, however, if the bladder is thin and dilated, or the vesical orifice of the ureter is enlarged by ulceration, regurgitation of urine from the bladder into the ureters may occur.

2. The acute inflammation of the kidneys which so frequently determines the fatal issue in diseases and injuries of the lower urinary tract is due to the infection of the kidneys by pathogenic micro-organisms. This renal infection is in the large majority of cases preceded by the occurrence of cystitis, and one or more of the organisms associated with this condition are present in the urine. Of these organisms, the most important, especially in so far as the secondary renal infection is concerned, is the *Bacillus coli communis*. But other pyogenic organisms may be present, and very frequently the infection is a mixed one (*see PYOGENIC BACTERIA*). The pyogenic organisms are often associated with others, such as the *Micrococcus ureæ*, causing decomposition of urea with ammoniacal change in the urine. This condition of the urine is often present, but the organisms which cause it are not to be regarded as essential elements in the secondary infection of the kidneys. It is undoubtedly true that ammoniacal urine may be found in the pelvis of the kidney, but secondary nephritis may occur in cases in which the urine has throughout been acid in reaction.

The most common route by which the infection of the kidney takes place is the lumen of the ureter. From what has been said above it will be

seen that it is only in exceptional cases that the infection is due to actual regurgitation of infected urine from the bladder into the ureter; in the absence of such regurgitation invasion by micro-organisms is doubtless favoured by the existence of catarrhal inflammation of the pelvis of the kidney and of the ureter, in consequence of which threads of mucus may occupy the vesical orifice of the ureter; along these the organisms find their way to the upper urinary passages, finally extending into the substance of the kidneys, where they may be demonstrated in the renal tubules.

Secondly, the infection of the kidneys from the lower urinary tract may occur by way of the lymphatics. Lindsay Steven long ago demonstrated by injection the continuity of the lymphatics of the bladder with those of the ureter, and these again with lymphatics in the superficial part of the cortex of the kidney and beneath the capsule; and in a fatal case of cystitis he demonstrated the presence of micro-organisms in the whole length of this lymphatic tract. Such a mode of infection may serve to explain certain cases of secondary suppurative nephritis not accompanied by pyelitis.

Thirdly, suppuration in the kidney secondary to an infective process in the lower urinary tract may result from a blood-infection, and thus be pyæmic in nature. Such a renal infection is in no way different from that which may follow infective processes not occurring primarily in the urinary tract, and will not be further considered here.

Certain phenomena occasionally arising as complications of various injuries and diseases of the lower urinary tract were at one time attributed to reflex disturbances of the renal circulation. Among the phenomena especially liable to occur after such procedures as the passage of a catheter or the dilatation of a stricture, which have been explained in this way, are: (1) fatal suppression of urine associated with intense congestion of the kidneys; (2) temporary arrest of the secretion of the kidneys followed by hæmaturia; and (3) the occurrence of rigors. Although the possibility of the occurrence of a reflex disturbance of the renal circulation in such cases has not been disproved, there is increasing evidence in support of the view that these rapidly developed and often fatal complications are the result of a general infection or toxæmia. As a striking instance of such a rapid infection, may be mentioned a case recorded by Albarran. A young man, upon whom internal urethrotomy had been performed for stricture of the urethra, had a violent rigor one hour and a half after the operation, the temperature rising to 104.4° F. Further rigors occurred, and the patient died twelve hours after the operation. The *Bacillus coli communis* was found in the blood, in the whole length of the urinary tract, and in the different organs. The congested state of the kidneys may in such cases be the result of a general toxæmia, and not, as formerly supposed, of a simple reflex disturbance.

ANATOMICAL CHARACTERS.—The consecutive inflammations of the kidneys are met with in four forms.

I. Chronic interstitial inflammation, followed by absorption of the medullary portion, and later by stretching and thinning of the cortex, without pyelitis.—This condition is the uncomplicated effect of obstruction to the free flow of urine, and of the consequent increased urinary pressure. It is

most frequently met with in cases of pressure on the ureter from without. In diseases of the bladder and urethra it is almost always complicated by an acute attack of interstitial inflammation, which is the immediate cause of death, and which more or less conceals the appearances about to be described. In the early stage there is slight dilatation of the ureter and pelvis of the kidney. The kidney itself is increased in size; the capsule separates without difficulty, but may leave the surface somewhat wanting in its natural smoothness. The venous stars on the surface are often clearly marked, the cortical substance being of a pale pinkish white or sometimes yellowish colour. On section the cortex is found to be wider than natural. The medullary portion is usually pale, like the cortex, but the large veins at the cortico-medullary junction are often distended with blood. The kidney-substance is tougher than natural. The Malpighian bodies can usually be clearly seen, sometimes as red dots. Microscopical examination shows an overgrowth of the interstitial connective tissue, which, especially around the Malpighian bodies, is richly cellular. The epithelium shows no change. The next stage observed is commencing absorption of the medullary portion; the ureter, pelvis, and calices become still more distended; the papillæ are first flattened, and then the pyramids become hollowed out. This is a process of pure absorption, there being no ulceration. The cavity formed by the dilated calyx, and the hollow left by the disappearance of the pyramid, are lined by a continuous smooth layer of opaque white mucous membrane. In the final stages the cortex in its turn becomes thinned and stretched, until at last the whole kidney may be dilated into a large sac, one side of which is smooth, being formed by the thickened walls of the dilated pelvis, the other deeply sacculated, each sacculus corresponding to a lobe of the kidney. On this side the wall is formed of the thinned and stretched cortex, sometimes no thicker than a shilling, to which the capsule, now thickened and opaque, is firmly adherent. In the later stages the microscope shows the same abundant small-cell infiltration, with the development of a greater or less amount of fibroid tissue. The Malpighian bodies show marked changes. The capsules, instead of being delicate and membranous in structure, become greatly thickened, apparently by dense fibroid tissue formed around them in concentric layers. As this change progresses the vessels may become strangulated and finally obliterated; the glomerulus then shrivels, and is represented by a circular body almost homogeneous in the centre, but marked by a few curved lines indicating the situation of the obliterated vascular tufts. Around this centre is a concentrically laminated layer, formed by the thickened capsule. Even in the most advanced stages the epithelium of the convoluted tubules shows remarkably little change beyond being somewhat flattened.

If at any stage obstruction to the free flow of the urine be removed, the process ceases. The new tissue between the tubules undergoes development into dense fibroid tissue, the process being accompanied by great contraction. The kidney, from being increased in size, may thus become much smaller than natural, excessively tough and puckered, and irregular in form. If the distension have reached the most extreme stage before the primary disease is relieved, the kidney may finally be repre-

sented merely by a small nodule of dense fibroid tissue.

II. *Acute diffuse interstitial nephritis without suppuration*.—In this variety both kidneys are usually affected. The kidney is increased in size, and the surrounding fat is sometimes oedematous and adherent to the capsule. When removed, the capsule separates without difficulty, but often leaves the surface coarse; it is somewhat opaque, and often marked with ramifying vessels. The surface is usually of a pale, yellowish-white colour, often mottled with dark red, or in some cases the red may greatly predominate. The mottling often corresponds to the bases of the lobules of the gland, some of which are paler than others, in consequence of the more advanced condition of the interstitial inflammation. On section, the cortex presents the same colour and mottled appearance as the surface, and is evidently swollen. The pyramids may be pale, but are often dark red, contrasting strongly with the paler cortex. The Malpighian bodies are usually clearly visible, and may show on the cut surface as red dots. The consistence of the kidney is unnaturally soft, unless previously to the acute attack it has been indurated by the chronic process first described. The pelvis may be merely dilated, and its mucous membrane opaque, but more commonly it is marked by ramifying vessels, and presents evidence of chronic congestion, in the form of pigmentation, thickening, and induration. In other cases it is intensely injected, sometimes covered with a membranous exudation mixed with phosphatic deposit, and the urine it contains may be foul and ammoniacal. In consequence of the pallor of the kidney sometimes met with as a result of the emptying of the vessels after death, this form of kidney may, without the microscope, be confounded with the large white or the fatty kidney.

On microscopical examination the following conditions are found. Between the tubules is a very abundant cellular exudation, especially around the Malpighian corpuscles. So far the condition is merely an intensification of that described as resulting from increased urinary pressure. The change is not uniform; in one part the renal structure may appear almost normal, and close by the new cells may be heaped up to such an extent as nearly to conceal the tubules. In the pyramidal portion a similar condition is met with. The renal epithelium throughout is slightly more cloudy than natural, and somewhat swollen, but the nuclei of the cells are readily to be seen in sections prepared in the ordinary way. The adhesion of the epithelium to the membrana propria is somewhat lessened, so that unless considerable care be taken it will wash out in preparing the specimen. Fibrinous casts may be seen here and there in the tubules; and occasionally small round cells, resembling those outside the tubules, may be seen within them.

III. *Acute interstitial nephritis with scattered points of suppuration*.—*Suppurative nephritis or pyelo-nephritis*.—This form of inflammation of the kidney is the usual cause of death in fatal cases of disease of the bladder or urethra, in which infection of the contents of the bladder has occurred. It thus comes to be one of the most common fatal complications in cases of injury or disease of the spinal cord, with paralysis of the bladder. The naked-eye appearances are the following: The surrounding fat may be oedematous and unnaturally adherent to the capsule. The whole kidney is considerably swollen,

and its substance soft. The capsule is opaque and thickened, and marked by fine ramiform injection. It separates easily, but tears the kidney-substance in so doing. As it peels off, yellowish-white spots, surrounded by a red zone, come into view. Some of these are minute drops of pus escaping from the small abscesses as the capsule is stripped off, others are on the point of breaking down into pus, but are still solid. These abscesses are grouped together in areas corresponding to the bases of the lobes of the kidney. If the veins can be recognised, the abscesses will often be seen to correspond to the points at which the interlobular veins appear on the surface. On section, the cortex is seen to present much the same appearance as in the last form of kidney, but in addition yellowish streaks are seen passing from the points of suppuration deeply into the cortex, and often into the medullary portion. These streaks correspond to the course of the interlobular vessels. They differ from embolic infarcts in their great length compared with their breadth. The pelvis is usually in a condition of most intense inflammation; the mucous membrane is often covered with a layer of exudation mixed with phosphates, and the contents, composed of urine, blood, and mucus, are in some cases foul and ammoniacal. Cases, however, do occur in which a similar condition of suppuration in the kidney is met with without pyelitis. In these it is probable that the pyogenic organisms reached the kidney by the lymphatics.

Occasionally the kidney is surrounded by a large abscess, arising from a perforation of the pelvis. More frequently one of the superficial abscesses in the cortex bursts beneath the capsule, and gives rise to a large collection of pus separating the capsule from the kidney.

The microscope shows the small-cell infiltration between the tubules in a still more intense form than in the varieties before described. In the areas of suppuration the kidney-substance has entirely disappeared, and its place is occupied by leucocytes packed closely together. In the central parts of these accumulations of small round cells the intercellular substance has softened, and the formation of pus has taken place. The amount of general interstitial change varies considerably; sometimes between the areas of suppuration the kidney-substance is almost healthy, in other cases there is a very marked general interstitial inflammation. The epithelium shows the same changes as in the last variety.

The micro-organisms which cause these acute inflammations of the kidney are found chiefly in the renal tubules, and in many instances form dense masses completely plugging the straight tubules and even extending into the convoluted tubes of the cortex. The organisms are also found in the lymph-spaces between the tubules in the pale streaks reaching from the medulla to the cortex along the course of the interlobular vessels. In pyæmia the organisms are very commonly seen plugging the looping vessels of the glomeruli, and occasionally some have found their way into the tubules, but in the acute renal inflammations belonging to the group under consideration the organisms are not found in the blood-vessels unless the direct infection of the kidney from the lumen or lymphatics of the ureter is complicated by an indirect infection through the blood-stream.

IV. *The cicatricial kidney*.—This is the result of recovery from one of the preceding conditions—probably only from one or both of the first two, as,

if the disease reach the stage of suppuration, the patient is hardly likely to survive. The kidney is shrunken, irregular in form, and marked by deep cicatrices. The substance is excessively tough, and the capsule firmly adherent. Small cysts may be scattered through its substance, which are supposed to result from strangulation of the tubules. The microscope shows a great excess of dense fibroid intertubular substance, and numerous obliterated glomeruli.

The varieties of kidney here described may be combined in various ways, and the naked-eye and microscopic appearances are modified accordingly. It is in fact more usual than not to find that the acute inflammatory affections occur in a kidney already more or less altered as the result of simple increase of tension. Thus a dilated kidney may suffer from acute diffuse interstitial inflammation, with or without suppuration; or a cicatricial kidney may, from a return of the primary disease, again suffer from an acute attack.

SYMPTOMS.—*Simple chronic interstitial nephritis*, with dilatation of the kidney from increased urinary pressure, gives rise to but few symptoms, and is very difficult to recognise. The most important signs are, that the quantity of urine secreted is increased, and its specific gravity lowered. The whole urine passed in twenty-four hours should be collected, and the specific gravity taken. There may be a trace of albumen, or it may be entirely absent. A few hyaline casts may be present, but they are by no means constant. The exact state of the urine is often concealed by the mucus, blood, and pus from the lower urinary tract. It is surprising how much urine is secreted by a kidney which is reduced to a mere sac, with no pyramids and a cortex no thicker than a shilling. In some cases the distended kidney may be recognised by palpation, but this is not common. It is not accompanied by hypertrophy of the heart, nor by marked increase of the arterial tension.

Although in itself not productive of definitive symptoms, this form of chronic renal disease is of great practical importance as a predisposing cause of such serious complications as rigors and suppression of urine after any operative interference upon the lower urinary tract.

Subacute interstitial nephritis gives rise to more marked symptoms. It runs an irregular course, often lasting for weeks or even months, and terminating either in recovery, or in a final acute attack with suppuration. If the disease arise as the direct result of some operation on the lower urinary tract, its commencement is usually marked by a rigor; in other cases it comes on more gradually, with frequent chills but no actual rigor. The temperature is high at night, reaching 101° to 102° F., but it falls towards morning, so that if it be only taken at that time, the elevation may be completely overlooked. The patient becomes weak and languid, and emaciates rapidly. He loses appetite, and there may be nausea or occasional vomiting. There may be diarrhoea, but this is by no means constant. The mucous membrane of the mouth becomes clammy, and the tongue foul, with a tendency to dryness. In severe cases the tongue becomes dry and brown, and sordes form on the teeth and lips. The skin is usually moist and clammy, and there is not the dryness so frequently met with in other forms of renal disease. There is no oedema. In rare instances the swollen kidney

may be felt by palpation in the loin, and tenderness may be elicited on deep pressure. The patient may complain of pain in the lumbar region, but this symptom is of little value, as it is often absent, and may arise from many other causes than renal disease. The pulse presents nothing characteristic. The patient frequently sinks into a drowsy state, somewhat resembling the effect of an over-dose of opium; but true coma is rarely, if ever, present, and convulsions never occur. The urine is passed in fair quantity, often in excess of the normal amount. The amount of albumen is never very great, but it is usually difficult to estimate accurately how much is renal, and how much is derived from blood or pus from the lower urinary tract. Microscopical examination may show hyaline casts, or occasionally pus-casts; renal epithelium is also frequently met with; but all microscopical examination is rendered difficult by the presence of mucus and pus from the lower urinary tract. If the primary disease be either removed or relieved by treatment, the symptoms gradually subside; if not, they remain without much change till the patient gradually dies exhausted, or an acute attack, rapidly leading to suppuration of the kidney, puts an end to the case.

Acute interstitial nephritis with suppuration most frequently forms the fatal termination of the variety of disease just described, but it may occur without any previous symptoms. The invasion is marked by a severe rigor, often occurring within a few hours of some operation on the lower urinary tract. The rigor is accompanied by great elevation of temperature, and followed by profuse perspiration, during which the temperature falls, perhaps below normal; but it soon rises again, and remains slightly raised, with evening exacerbations. The rigor may be repeated during the progress of the case at irregular intervals. The general symptoms resemble in every respect those just described as indicative of subacute interstitial nephritis, but they are increased in intensity. The strength rapidly fails, there is great emaciation, the pulse becomes feeble, and the tongue 'like a piece of broiled ham.' There may be occasional vomiting and diarrhoea. As the fatal termination approaches, the temperature falls often considerably below normal, the skin becomes cold and clammy, and the patient sinks into a drowsy condition, seldom deepening into actual coma. Although the patient is often said to be dying of 'uræmia,' there are none of the uræmic symptoms observed in acute Bright's disease. There are no convulsions or actual coma, and no oedema. The urine is usually so foul as to defy accurate examination, either chemically or by the microscope. It is secreted in fair quantity to the end of the case. Pus and blood are always found in it, but it is impossible to say whether they come from the kidney or from the lower urinary tract. Renal epithelium and pus-casts are occasionally met with.

DIAGNOSIS.—As already stated, the existence of the more chronic secondary renal inflammations can be determined only by a careful examination of the urine. In the acute forms, especially when accompanied by suppuration in the kidney, the general symptoms may in themselves be indistinguishable from those occurring in many other forms of septic infection or toxæmia. As a rule, however, their association with septic conditions of the lower urinary tract serves to indicate their nature. Severe cystitis without renal infection

may, however, cause marked general symptoms, and the examination of the urine, except by the detection of pus-casts, will not serve to show whether or not the kidneys are involved. The effect of treatment may, however, in such cases indicate whether the symptoms are the result of the cystitis alone. Catheterisation of the ureters and the separate examination of the urine secreted by each kidney has been used as a means of diagnosis, but for many reasons the practical utility of this method must be very limited in cases of this nature.

PROGNOSIS.—This depends, in the chronic or subacute form, entirely upon the possibility of removing or relieving the primary disease. After suppuration has commenced in the kidney, the chance of recovery is very remote.

TREATMENT.—The most essential element of the treatment is to remove the cause if possible, but the act of doing so is seldom unaccompanied by the danger of increasing the disease, involving, as it often does, severe operations upon the urinary organs, as lithotomy, lithotripsy, or internal or external urethrotomy. These operations would of course, if possible, be avoided if the renal symptoms were at all marked. The fatal termination being in almost all cases associated with cystitis and extension of the inflammatory process to the pelvis of the kidney, it is needless to point out that our best hope of preventing consecutive renal inflammation lies in the prevention of cystitis by scrupulous attention to cleanliness in the instruments used. This cannot be too much insisted upon in the management of cases of paralysis of the bladder from injury or disease of the spinal cord. The catheters used should, if possible, be of soft red rubber, which is not damaged by boiling or by solutions of carbolic acid. Paraffinum Liquidum is the best lubricant and can be efficiently sterilised by heating in a test-tube; and before any instrument is passed the meatus should be cleansed with a weak mercurial lotion.

If cystitis occur this must be treated without delay, in order, if possible, to restore the healthy condition before exhaustion has taken place. The most important element in the treatment is the daily irrigation of the bladder with a non-irritating antiseptic, such as a boiled solution of boric acid. *See* **BLADDER**, Diseases of.

If the symptoms of subacute interstitial nephritis are present, the patient will frequently derive much benefit from a pure milk diet. At the same time small doses of opium seem to promote the action of the skin, and so to relieve the kidney without producing the dangerous effects so much to be feared in Bright's disease. The action of the skin may at the same time be still further promoted by vapour-baths. The bowels should be kept freely open. Counter-irritation, either by dry-cupping or mustard-poultices over the loins, followed by hot fomentations, is frequently of use. When the symptoms of the acute form are well marked, operations to relieve the cause only hasten the fatal event. By careful nursing, and the treatment above described, the symptoms may be so far reduced in intensity as to render an operation for the removal of the cause justifiable.

MARCUS BECK.

RAYMOND JOHNSON.

KIDNEY, Cystic Disease of.—The presence of cysts in the kidney may co-exist with other lesions, or they may constitute the sole morbid

change. In the former case the cysts are usually few in number, small in size, and scattered. Where cystic disease is the only morbid change present the formation of cysts may be so widespread that but little appearance of renal tissue is left, although even in these cases a considerable amount exists in a compressed form between the cysts.

I. Scattered single cysts varying in size from a pin's head upwards are not uncommonly seen in the cortex of an apparently healthy kidney. They are much more abundant, however, in the granular kidney and in the contracted form of Bright's disease (*see* **BRIGHT'S DISEASE**). In a few instances of granular kidney the formation of cysts is more widespread, so that a score or more may be present in a single kidney. In these cases the size of the cysts varies considerably. They are most marked in the cortex and frequently project from the surface, their walls being thin and their contents a clear, yellowish, albuminous fluid, though in some cases this has undergone a colloid or gelatinous degeneration. Haemorrhage into the cysts occasionally takes place; the contents of these will be discoloured with altered blood. The cysts present in granular kidney may in exceptional cases be very numerous. They are never arranged with any great regularity, and while a large number may be found in one kidney, only a few may be present in its fellow. These cysts, however large and numerous, are essentially similar to the microscopic cysts found in granular kidney and in chronic Bright's disease, which owe their origin to dilatation of portions of the renal tubules. The larger cysts also owe their origin to the dilatation of the renal tubules, although in the fluid they contain, as in that of a hydronephrosis, but small quantities of urea are present. These cysts, especially when large, are lined by a layer of cubical or slightly flattened epithelium, the cells of which are usually hyaline. The presence of these cysts in granular kidney is a matter of no clinical importance. Occasionally thick-walled single large cysts, the size of an orange, are found. Usually such cysts involve one or other extremity of the kidney, and the renal tissue is spread out in an irregular manner so that one wall of the cyst, usually the anterior, is thinner and contains less renal substance than the posterior. The presence of these large single cysts is not usually accompanied by any other morbid condition of the kidney except that it may be malformed. These cysts are also supposed to owe their origin to obstruction of the renal tubules, but it is possible that some cases are dependent on the formation of a cyst as the result of external violence causing a rupture of the renal substance, although, speaking generally, wounds of the kidney heal readily. These cysts are of no great clinical importance except that the cyst may be of sufficient size to be recognised by abdominal palpation, and may be confounded with an enlarged gall-bladder or with some other variety of renal tumour.

Rare forms of cystic disease are seen involving the medulla of the kidney, the cysts being more irregular in their shape than in their distribution, and it is probable that some of these cases are adenomata of the kidney undergoing cystic degeneration.

II. The term '*cystic disease*' is generally limited to a condition in which the whole kidney consists of a congeries of cysts of varying size. Notwithstanding the enormous development of cysts the organ

retains its outline, but otherwise presents the appearance of a large bunch of grapes. Two forms of this general cystic disease may at any rate be recognised, one in which the condition is congenital, the other in which the morbid process is only detected in adult life or in the aged. In both forms of the disease both kidneys are usually affected, although cases have been described where the disease was unilateral, or at any rate where it was much more advanced on the one side than on the other. In the congenital form the kidneys are of very varied size, in some cases not more than double or treble the normal, in others the increase is so great as to produce difficulty in labour. The congenital form has been supposed to be due to dilatation of the straight tubules as a result of inflammation brought about by presence of uric acid, the atresia of the straight tubules leading to the development of retention-cysts. Another view of the disease is that the cyst-formation occurs in the persistent remains of the Wolffian bodies. Malformation of the kidney and of the lower urinary tract is often associated with the presence of congenital cystic disease; and malformations in other parts of the body, such as the presence of supernumerary fingers and toes, have been described.

In the variety of the disease seen in adults, the kidneys are greatly increased in size, consisting of a mass of cysts varying from one-eighth to three-quarters of an inch in diameter. The cysts are entirely distinct from one another, and their contents cannot be emptied by pressure. The fluid in the cysts is usually amber-coloured, containing traces of urea and a variable amount of proteid matter. In some cases the colour of the fluid is altered by the presence of extravasated blood. All distinction between the cortex and the medulla is lost, the kidney apparently consisting of a uniform mass of cysts of irregular size; but on section the renal tissue is found in considerable quantities between the walls of the contiguous cysts. In some cases this renal tissue is normal in appearance, in others it presents changes similar to those seen in the granular kidney.

Small cysts may also be present in the mucous membrane of the pelvis of the kidney, and it is not uncommon for cysts to be present in other organs of the body, especially the liver, the brain, and sometimes the thymus.

In cases of cystic disease the heart and the arteries may show changes similar to those seen in cases of granular kidney; but this is not invariably the case, and it is probable that, when present, these vascular changes are dependent on the fact that the remaining renal tissue spread out between the cysts has undergone the same changes as those seen in the granular kidney.

The pathology of general cystic disease in adults is obscure. Some have thought that these cases are either really congenital and have remained latent for a number of years, in some cases throughout life, or else that their mode of origin is similar. Others have thought that the disease is of the nature of a growth, more especially owing to the fact that cysts are found in other organs such as the liver and brain. It is unquestionable that extensive cystic disease of some kind may result from the presence of adenomata.

SYMPTOMS.—In many cases no symptoms at all are produced, death being dependent on some other morbid process. It is probable that the disease

always runs a long latent course, symptoms occurring more or less suddenly, and sometimes only towards the end. In some cases the first suspicion of the presence of cystic disease is the occurrence of acute uræmia. More usually, however, before the onset of uræmia other symptoms have been present, such as loss of strength, emaciation, and pain in the back. Hæmaturia, often profuse, is not uncommon. These symptoms, together with the presence of bilateral tumours and the secretion of an abundant pale urine containing traces of albumen, are the most characteristic features of the disease. In one case observed by the writer the condition was diagnosed four years before the onset of fatal uræmia. In some instances the renal tumour produces varying degrees of intestinal obstruction, as a result of pressure on the colon. Cystic kidney commonly causes death by producing uræmia; this is usually of the acute type, and epileptiform fits and coma are frequent. In some cases, however, latent uræmia similar to that seen in calculous obstruction is produced, and in these cases death may occur quite suddenly from respiratory failure.

DIAGNOSIS.—Abdominal palpation usually readily reveals the existence of this condition; but difficulties may present themselves where the disease is unilateral or more developed on one side than on the other. One of the characteristic features of the tumour is its lobulation. The disease may be confounded with hydatids; and in some cases, owing to the presence of hæmaturia, malignant disease of the kidney may be diagnosed.

PROGNOSIS.—The prognosis of the disease is very uncertain, and depends mainly on whether symptoms are present. If these are of the uræmic type, life is not usually prolonged for more than a few months, and death may ensue very rapidly.

TREATMENT.—The fully developed disease is beyond cure, and all that can be done is to treat such cases hygienically and dietetically, like cases of Bright's disease. Where the disease is unilateral the affected kidney may be removed, but such cases are very rare, and nephrectomy should not be performed where there is evidence of bilateral disease, firstly, because in such cases operative interference may bring about fatal uræmia, and, secondly, because the kidney, although extensively diseased, may still perform its functions, though to a limited extent.

KIDNEY, Embolism of.—**ÆTIOLOGY.**—Infarction of the kidney may follow the detachment of clots or vegetations from the interior of the heart or large arteries, or of fragments of calcareous matter from atheromatous ulcers in the aorta. Microscopic emboli may be due to the lodgment of micro-organisms in the kidney. The arrangement of the arteries in the kidney is such as to lead inevitably to infarction if any of them become occluded. Results somewhat similar occasionally follow thrombosis of the renal artery. See p. 838.

Renal embolism is therefore a common consequence of thrombosis in the left auricular appendix or in the left ventricle, and of valvular disease of the heart, especially when due to malignant endocarditis. In rare instances the embolus may consist of a piece of a clot detached from the interior of an aortic aneurysm. Usually one or more of the interlobular arteries of the kidney becomes blocked, but in some cases the embolus is of large size and blocks one of the main divisions, or even the entire renal artery.

MORBID ANATOMY.—The results of renal infarction depend chiefly on the nature of the embolus. See **EMBOLISM**.

In cases of chronic heart-disease extensive and repeated embolism may occur, leading to the formation of a considerable number of large infarcts in the kidney; and their subsequent absorption leads to great deformity and puckering of the organs.

SYMPTOMS.—These are frequently so trivial as to escape observation. The most characteristic symptoms are the sudden occurrence of pain, together with albuminuria, the extent of the latter depending a good deal on the extent and character of the embolism. In a considerable number of cases sudden hæmaturia occurs, but it is not such an invariable accompaniment as albuminuria. The pain is usually of moderate severity, and is felt in the back and loin. It is not so definite in its localisation as that seen in renal colic, but may be confined definitely to one side. The albuminuria and the hæmaturia are both characterised by their sudden appearance and equally sudden disappearance. The hæmaturia is usually only sufficient to impart a smoky colour to the urine; copious hæmaturia is rare.

In some cases the occurrence of renal embolism is first revealed by the occurrence of sudden pyuria. This is necessarily confined to septic cases. The pyuria also is characterised by its sudden appearance and disappearance, and is dependent on a renal abscess rupturing into the renal pelvis and being discharged with the urine. In septic cases the onset of renal embolism is marked by the occurrence of rigors and high fever.

DIAGNOSIS.—Renal infarction has to be distinguished especially from passive congestion of the kidney and from acute Bright's disease. The principal difficulties in diagnosis arise in cardiac cases. Renal embolism is usually recognised by the suddenness of onset and transitory duration of its main symptoms, and by the presence of an underlying disease capable of causing it. Absence of renal dropsy is often a means of distinguishing infarction from the onset of an acute inflammation.

PROGNOSIS.—The prognosis depends entirely on the cause. In simple morbus cordis it is not in itself a serious condition; but in septic cases it is serious, in that it affords a clue to the existence of a graver underlying disease.

TREATMENT.—There is no special treatment for this condition, but it is essential to separate it from acute nephritis, inasmuch as it does not require the treatment necessary for that affection.

KIDNEY, Fatty Disease of.—Fatty disease of the kidney consists of a simple fatty degeneration of the epithelial elements of the kidney, and is a condition which is not characterised by any recognised symptoms. It is usually part of a widespread fatty degeneration involving also the heart and liver. See **FATTY DEGENERATION**.

MORBID ANATOMY.—The kidneys are usually normal in size, their surface is smooth, the capsule strips readily. There is no congestion. The surface of the organ is paler than naturally and has a greasy appearance, and on section the cortex is also pale and yellowish. On microscopical examination the epithelial cells show the well-known features of fatty degeneration. The Malpighian bodies, the vessels, and the stroma are not affected.

SYMPTOMS.—It is said that the quantity of urine is apt to be diminished. Albuminuria is not usually

present, but it has been asserted that small quantities of fat are present in the urine; this, however, may also be seen in health.

DIAGNOSIS.—The condition can only be suspected from the existence of causes capable of causing fatty degeneration and from the presence of fatty degeneration in other organs, and more especially the liver.

PROGNOSIS.—The involvement of the kidneys is not known to affect materially the prognosis of the general disease, the involvement of the other organs, especially the heart, being a more important factor in the case.

TREATMENT.—The treatment is that of the underlying condition.

KIDNEY, Granular.—The granular kidney presents some resemblances to that variety of Bright's disease described as the contracted white kidney (p. 217), inasmuch as in both the cortex is greatly diminished in thickness, and owing to the degeneration of the epithelial structures in the kidney and the overgrowth of fibrous tissue the surface of the organ in both instances is granular.

At least two forms of the true granular kidney may be recognised, one where the morbid process is mainly limited to the kidney itself, and the other where the renal changes are accompanied by very extensive degeneration of the arterial system; but in both forms the renal arteries are profoundly affected.

ÆTIOLOGY.—In many cases the ætiology of granular kidney is really that of arterial degeneration. In such cases, alcoholism, syphilis, heredity, and perhaps laborious occupations, play a part. The disease affects men more often than women, and is especially common after middle life, being rare under twenty-five, and uncommon before forty. It may also be produced by the action of toxic substances, especially lead and alcohol, and perhaps the poison of gout. The disease is said to be associated with excessive eating and also with prolonged mental anxiety.

MORBID ANATOMY.—The kidneys are usually smaller than normal, but great variations in size are seen; in many cases in which the disease is associated with extensive arterial degeneration, the kidneys are not so shrunken as in other cases in which the general arterial lesions are less developed. The weight of an affected kidney may be reduced to two ounces, but usually it is between three and four. The diminution in size is often greater than the diminution in weight, owing to the great overgrowth of fibrous tissue. The surface of the organ varies considerably in colour; in some cases it is of a uniform red colour, in others mottled. The surface is coarsely granular, and for this reason the term 'raspberry kidney' has been applied to it. The capsule is adherent, moderately thickened, and tears the renal substance as it is stripped off. The cortex is extremely narrow, frequently measuring not more than one-sixteenth of an inch. The medulla is deeply congested and the fat in the hilum abundant. The cortex may contain cysts varying in size from a pin's head to a cherry; in some cases great numbers of these cysts are found, in others only one or two. The cysts are filled with a yellowish albuminous fluid containing small quantities of urea. On section, the vessels stand out prominently, their walls being markedly and irregularly thickened. The vessels in other parts of the body show signs

of degeneration, such as a loss of elasticity and great thickening of the inner coat, dependent on an overgrowth of fibrous tissue in the subendothelial layers. Military aneurysms may be found in the cerebral vessels. On microscopical examination the kidney shows a general, but irregularly distributed, overgrowth of fibrous tissue, specially well marked round the glomeruli. Many of the latter are atrophied, the capillary tufts having undergone hyaline degeneration; in others there is a development of fibrous tissue in the capillary tuft itself. A few normal glomeruli may be found, and others in which the capillary tuft shows signs of cellular and fibrous overgrowth without any great thickening of the capsule. The circulation in the glomeruli is greatly interfered with, partly because of the fibrosis of the glomerular chamber and of the tuft, and partly owing to the thickening of the endothelial coat of the arteries. The tubules in many areas of the kidney are apparently replaced by fibrous tissue, the epithelial cells having disappeared and the walls of the tubules remaining collapsed. In many parts of the cortex the tubules are dilated, and in these the epithelium consists of cubical hyaline cells; in other parts the epithelium has undergone granular and fatty degeneration. The tubules of the medulla are less affected than those of the cortex. The vessels of the kidney show considerable changes in all the coats; peri-arteritis is present to a considerable extent, but the inner coat is especially thickened, by the formation of fibrous and elastic tissue in the subendothelial layer, so that this coat often equals in thickness all the other coats of the vessel together. The middle coat also may be thickened by the formation of an excess of muscular tissue. The interstitial tissue throughout the kidney is commonly infiltrated with small round cells. The heart is hypertrophied; the degree of hypertrophy varies with, and is probably dependent on, the extent of the general arterial degeneration. The amount of cardiac hypertrophy bears no relation to the degree of atrophy of the kidney. Hypertrophy affects the left side of the heart especially, but in any case in which the enlargement of the heart is at all considerable, the right side is also affected. The cardiac hypertrophy is in great part dependent on an overgrowth of muscular tissue; in some exceptional cases, an irregular overgrowth of fibrous tissue may occur.

SYMPTOMS.—In a considerable proportion of cases the disease is absolutely latent, death occurring from some complication, and is only revealed at the autopsy. Thus, in one case, fatal cerebral hæmorrhage, and in another uræmic phenomena, often of extreme violence, may be the first indications of the existence of the malady. More usually the patient comes under observation presenting signs of a general failure of health such as weakness and emaciation, together with some headache and perhaps such cardio-vascular symptoms as palpitation and shortness of breath. Such patients are found to pass eighty or one hundred ounces of clear, pale urine having a specific gravity of 1010, and containing a small quantity of albumen. Albumoses may be present in the urine in addition to serum-albumen and serum-globulin. In another group of cases the early symptoms are of a cardiac type, such as shortness of breath, palpitation, præcordial pain, and œdema of the lungs and lower extremities. In this way the disease presents symptoms similar to those seen in mitral regurgitation, and it is not uncommon

for cases of granular kidney with secondary cardiac failure to be looked upon clinically as cases of mitral regurgitation with renal congestion.

The most frequent type of the disease is that in which the patient presents general vague symptoms of ill-health together with symptoms referable to the disturbance of the circulatory system. In some instances the general symptoms of ill-health are so vague as to present a close resemblance to those seen in neurasthenia. The malady has generally advanced to a very considerable extent before it produces symptoms sufficient to lead to its recognition.

Hæmorrhage may also occur as an early symptom. This most frequently takes the form of epistaxis. Cerebral hæmorrhage is likely to occur in cases in which the morbid lesions in the kidney are less marked than those in the general arterial system. Hæmorrhage into the retina is not uncommon, and may be the first symptom. In rare instances copious hæmaturia occurs, and it is probable that in some of these cases the hæmorrhage really comes from the mucous membrane and pelvis of the kidney, and is not due to acute inflammation. Purpura is a frequent complication.

The general wasting seen in granular kidney is sometimes as extreme as that seen in malignant disease, and is far more obvious than the emaciation accompanying other forms of renal disease where dropsy is present and masks it.

The urine in cases of granular kidney is usually albuminous, though in most instances the quantity of albumen present is not more than a trace. The quantity of albumen, however, varies at different times, and at some stages may be absent. This is most frequently observed in the early stages of the disease, but sometimes the urine may remain free from albumen during the fatal illness, and this may be so even when the patient dies from uræmia.

Albumoses in traces are frequently present, and a few instances have been described where these substances have been present in very large quantities. In some cases the albumosuria is dependent on the co-existence of bone-disease or of inflammatory processes in some other part of the body, or even of ovarian cysts. There are, however, cases of uncomplicated granular kidney in which large quantities of albumoses may be secreted by the urine. It has been supposed that in these cases the alimentary canal is the source of the albumoses, and that these are absorbed and remain unchanged owing to some anomaly in the processes of digestion and nutrition. See ALBUMOSURIA.

The heart in cases of granular kidney usually shows distinct signs of hypertrophy, often considerable in amount, and in not a few cases the hypertrophy is further complicated by the co-existence of mitral regurgitation owing to dilatation. The physical signs of hypertrophy may be more or less completely masked by the presence of emphysema, the latter being a common complication of this form of renal disease. In addition to the usual physical signs of cardiac hypertrophy, the heart-sounds are often considerably altered, the first sound being muffled, reduplicated, or presenting the well-known *bruit de galop*. The aortic second sound is markedly accentuated. The pulse shows the characteristic features of high tension, and in many cases in addition to this the arteries yield evidence of degenerative processes, and the radial arteries roll under the finger like pieces of whipcord. Marked structural changes in the vessels, sufficient

to be recognised clinically by the finger, are, however, by no means invariable, and are not so characteristic of granular kidney as the presence of a high-tension pulse. The arterial degeneration may often be detected from the examination of the fundus oculi owing to the rigid and thickened condition of the arteries; and it is not uncommon to see extreme congestion of one or more of the retinal veins produced by the pressure of a rigid artery crossing a vein. Papillitis, retinitis, retinal hæmorrhages, and all the features which characterise albuminuric retinitis, are frequently present in this disease.

DIAGNOSIS.—When uræmia occurs in a latent case, especially if it take the epileptiform type, the disease may be confounded with epilepsy. This can usually be excluded by an examination of the fundus oculi.

In the cases in which vague general symptoms only are present the disease may be confounded with neurasthenia or some more or less trivial gastric affection. Whenever symptoms of this character occur in middle-aged men, granular kidney should be suspected, and the state of the urine, the vessels, and the fundus oculi carefully examined.

In the cardiac type of the disease considerable difficulties present themselves in the differential diagnosis between granular kidney complicated by a failing heart and primary morbus cordis complicated by congestion of the kidney. Although in the latter case the urine is usually scanty, high-coloured, and contains a considerable quantity of albumen, cases are sometimes seen in which the percentage of albumen is small, resembling the condition present in granular kidney. Further, when granular kidney is complicated with a failing heart and dropsy, the amount of urine secreted is necessarily diminished. The condition of the vessels, the degree of tension, and the state of the fundus oculi furnish the most reliable evidence in making a differential diagnosis between the two conditions.

Granular kidney has been confounded with cerebral and cerebellar tumour. In all cases of suspected granular kidney it is essential that the urine should be repeatedly examined, as the absence of albumen based on a single examination is of little or no value in excluding the disease.

PROGNOSIS.—This disease must be regarded as an incurable malady, although patients suffering from it may in some instances live for many years, and even suffer comparatively little inconvenience. They are always, however, in imminent danger of succumbing to some complication, such as cerebral hæmorrhage or fatal uræmia.

In cases of the cardiac type the prognosis is always very serious, and also in those cases in which inflammatory complications, such as pericarditis, pneumonia, or pleurisy, are present.

TREATMENT.—The first essential in the treatment of granular kidney is to protect the patient as far as possible from strain, and especially from strain of his vascular system, as any sudden exertion may, owing to the serious arterial disease present, lead to the occurrence of cerebral hæmorrhage. For this reason, among others, care should be taken, when prescribing purgatives for these patients, that none are ordered that cause any severe griping or straining at stool, and it is probable that saline purgatives are the most efficient and suitable drugs in these cases.

The high tension should, if possible, be relieved. Warm baths and saline purgatives are efficient for this purpose, together with the regulation of the diet and the avoidance of stimulants. The only drugs which possess an efficient action in lowering tension are the nitrites and nitro-glycerin. Nitrite of amyl produces the most transitory effects, and is not very suitable. Nitro-glycerin and erythrol tetra-nitrate are more useful, owing to the fact that the effects produced are more lasting. Often, however, owing to the anatomical changes in the blood-vessels, these drugs produce but little relief. Venesection may be used for the same purpose in cases of extreme high tension associated with uræmic symptoms or even with cardiac distress, and it is notorious that a spontaneous hæmorrhage such as epistaxis often relieves these patients considerably. The best effects in the treatment of the high tension are usually obtained by promoting free action of the skin, free purgation with salines and careful dieting. The diet should be light, and these patients should be especially warned against eating large quantities of meat and highly seasoned foods. Alcoholic stimulants are harmful, and even such substances as tea and coffee should be taken in moderation owing to their stimulant action. It is impossible, however, in all cases to cut off alcoholic stimulants; they may be necessary, for instance, in some cases of the cardiac form of the disease. Any anæmia that may be present should be treated with iron and arsenic. Whenever cardiac failure has supervened, and the patient presents symptoms of mitral disease, the case must be treated on the usual lines, although such drugs as digitalis, strophanthus, strychnine, and cardiac tonics generally, causing increase of the blood-pressure, must be used with caution, since the heart is already failing as a result of increased arterial pressure, and all these drugs tend to increase arterial pressure. At the same time it must be remembered that their beneficial action on the heart often outweighs their effects on the arteries.

Wherever the presence of dropsy requires incision or puncture for its relief, extreme care must be taken to avoid septic complications, since granular kidney, like other renal diseases, leads to a diminished resistance on the part of the tissues. Residence in a warm equable climate during the winter months is as important in the treatment of granular kidney as it is in that of Bright's disease.

KIDNEY, Hæmorrhage in connection with.—Hæmorrhage may occur into the substance of the kidney as a result of traumatism, as a result of embolism, of acute inflammation, and from the presence of growths.

Submucous hæmorrhages in the renal pelvis are seen in cases of purpura, leucocythæmia, and granular kidney, and it is possible that the profuse hæmaturia sometimes seen in these diseases is dependent on hæmorrhage in this situation. See p. 621.

KIDNEY, Hydatid Disease of.—Hydatid disease involving the kidneys is rare, both liver and lung being more commonly attacked. The left kidney is rather more frequently affected than the right, and the cyst usually arises in the substance of the organ. In enlarging the cyst usually reaches the pelvis of the kidney. In rare instances it has enlarged upwards so as to perforate the lungs. There is no record of a cyst having burst into the

peritoneum. It is not uncommon for the cyst to cease growing. In other instances suppuration may occur as in other organs. When a hydatid cyst ruptures into the pelvis of the kidney the hooklets and daughter-cysts are passed in the urine, and may give rise to attacks of renal colic, but the cyst may reach a very large size before it ruptures. The discharge of the hooklets and daughter-cysts in the urine usually takes place paroxysmally, and may go on for many years. See *ENTOZOA*.

A tumour resembling a hydronephrosis may be produced, but the disease can scarcely be diagnosed unless hooklets are found in the urine or there is clear evidence of hydatid disease elsewhere. When hooklets are present in the urine the parent hydatid cyst is not necessarily in the kidney; it may be in the retroperitoneal tissue, but the combination of hooklets in the urine with attacks of renal colic is very suggestive of hydatid of the kidney.

The *prognosis* is on the whole favourable, owing to the fact that the great majority of these cysts, if they rupture, rupture into the pelvis and their contents are discharged.

The *treatment* is similar to that of hydatid disease involving other parts.

KIDNEY, Hyperæmia of.—Two varieties of congestion of the kidney are seen: (1) active congestion; and (2) passive congestion.

In congestion of the kidney the primary changes occur in the blood-vessels of the organ, but these may lead to secondary results in the kidney, especially if long-continued or severe.

ÆTIOLOGY.—*Active congestion* of the kidney is closely associated with nephritis, and is usually produced by the action of toxic substances on the organ. It is thought, however, that it may arise under other conditions, and more especially by reflex effects produced through the nervous system. Many poisons, such as cantharides, turpentine, carbolic acid, and mineral acids, produce acute congestion of the kidney. The poisons of scarlet fever and of other acute specific fevers produce the same result. Although many poisons, mineral and organic, produce acute congestion, their action is rarely limited to the blood-vessels. Some poisons, such as cantharides, produce marked effects on the blood-vessels; others, such as heavy metals, produce their main effects on the renal cells. Acute congestion of toxic origin is separated with difficulty from nephritis and Bright's disease.

Acute renal congestion produced reflexly through the nervous system is sometimes seen as a sequel to irritation of the lower urinary tract, as by the passage of a catheter. This rarely occurs where the kidneys are perfectly healthy, but it is liable to supervene if advanced renal lesions exist. It has been thought that congestion of the kidney may arise in some cases of excessive cardiac hypertrophy, e.g. aortic disease.

Passive congestion of the kidneys may be seen whenever the circulation through the venous system is interfered with. It is most commonly met with in cases of cardiac or of pulmonary disease, in which the right side of the heart is either primarily or secondarily involved. It may also be due to the pressure upon the vena cava, caused by diseases of the pericardium, abdominal tumours, or hepatic cirrhosis. The renal veins may be pressed upon by growths or aneurysms, and in rare instances thrombosis of the renal veins may occur as a result

of marasmus or of septic processes. Thrombosis of the renal vein may occur as a result of these causes when the kidneys are healthy; but it is also seen in certain renal diseases, especially the granular kidney and malignant disease. In rare instances the renal veins become thrombosed as a result of a phlebitis spreading from other parts, especially the pelvic veins.

MORBID ANATOMY.—In *active congestion* the kidneys are generally of normal size, or larger than normal, and in some very acute forms the distension may be such as to cause rupture of the capsule. The capsule strips off readily, leaving a smooth but congested surface. On section the vessels are found engorged, and the distended glomeruli can frequently be seen as bright red spots. Streaks of extravasation may also be visible here and there, which on microscopic examination are seen to be dependent on hæmorrhage into and between the tubules. The changes are more marked in the cortex than in the medulla. Microscopically degenerative changes may be found in the renal cells, and both the tubules and the interstitial tissue show the presence of extravasated blood. In *passive congestion* the anatomical changes depend very much on the duration of the disease. In the acute forms dependent on thrombosis of the renal veins the congestion of the kidney-tissue is extreme, and is especially marked at the junction of the cortex and the medulla. On microscopical examination blood is found freely extravasated in and between the tubules, and the cells of the kidney may have undergone complete necrosis. In the more chronic forms the kidney is enlarged, red and often tough, the capsule may be adherent, while, on being stripped, it leaves an uneven surface, although in the earlier stages the surface of the organ may be smooth. The congestion is always well marked in the medullary portion of the kidney, and the Malpighian bodies are not generally so distended as in active congestion. On microscopical examination the veins are found distended with blood, and extravasations into the interstitial tissue are especially marked in the medullary region. Where the congestion is at all severe the tubules themselves will also contain blood. The interstitial tissue is increased in amount, and the basement membrane of the tubules is thicker than normal. In many tubules the cells have lost their characteristic structure and have become hyaline and glass-like. In many cases it is difficult to distinguish with certainty between the results produced by mere passive congestion and those dependent on the co-existence of slighter forms of nephritis.

SYMPTOMS.—In *active congestion* true symptoms are frequently absent, and the condition is only revealed by an examination of the urine. In others the patient experiences some pain in the back, and this in exceptional circumstances may be severe. The urine is diminished in amount and contains albumen in variable quantity, large amounts sometimes being present. Blood is also frequently present, usually in small amount, but in some forms of acute congestion produced by toxic agencies, such as turpentine and cantharides, the amount of blood present may be large. Hyaline, granular, and blood-casts also occur. In the more severe forms of acute congestion suppression of urine may occur, but dropsy is absent and forms one of the means of distinguishing between acute congestion and acute Bright's disease.

In *passive congestion* the urine is diminished in quantity, often dark in colour, and contains albumen in varying amount, from a mere trace to a sixth or even a third of its bulk. Hyaline and granular casts are also present, and it is not uncommon for blood even in considerable quantity to be present in the urine. In many cases of passive congestion it is difficult to exclude other causes, especially toxic ones, and this may account for some of the higher grades of albuminuria seen, for instance, in pregnancy. In most cases of passive congestion the amount of albumen in the urine is small.

DIAGNOSIS.—*Active congestion* has to be separated from Bright's disease and from infarction of the kidney. It is sharply marked off from the severe forms of Bright's disease by the absence of dropsy and also by the rapid manner in which the condition subsides and health returns.

Passive congestion has also to be separated from Bright's disease. The difficulties that present themselves occur mainly in cardiac cases, in which it may be difficult to determine whether we have to deal with a primary cardiac case, with secondary congestion of the kidney, or a primary renal case with secondary cardiac failure. In passive congestion and in Bright's disease the urine may be scanty, but in passive congestion it is usually of high specific gravity, whereas in Bright's disease, even if scanty in amount, the specific gravity is usually low. This statement, however, is not always accurate, and cases may be seen of congested kidney dependent on heart-disease where the urine is of low specific gravity; these, however, are exceptional. In passive congestion, although blood may be present even in some abundance, epithelial casts do not occur, the only casts present being hyaline and granular.

PROGNOSIS.—*Active congestion* of the kidney frequently subsides even when dependent on toxic causes, such as turpentine and cantharides; reflex active congestion when occurring in diseased kidneys is, however, extremely serious. The prognosis of *passive congestion* must necessarily depend almost entirely on its cause. It is usually a serious complication of morbus cordis and a sign of plethora of the venous system, although extreme anasarca may occur in cardiac cases without signs of marked congestion of the kidney, and conversely cases are seen where the renal congestion is apparently greater than the congestion of the vessels generally. Passive congestion in cardiac disease affects the prognosis unfavourably, owing to the extreme difficulty of promoting diuresis in such cases.

TREATMENT.—It is customary in *active congestion* to apply dry cupping or hot fomentations over the loins, and in this way the pain may be relieved. Measures promoting the activity of the skin and of the bowels must be used, and the diet must be reduced to a minimum in order to spare the kidneys as much as possible. In the more severe forms the malady requires treatment identical with that of acute Bright's disease.

In *passive congestion* treatment must be directed to the cause of the condition, and many such cases improve greatly under the administration of digitalis or caffeine, drugs which increase the activity of the kidney. Digitalis is especially of service owing to the fact that it produces its diuretic effects by improving the general circulation. Saline purgatives are often of great service, and the

activity of the skin should be promoted by hot-air and warm baths.

KIDNEY, Hypertrophy of.—The term 'hypertrophy of the kidney' is usually applied to a condition in which the organs are increased in size without the presence of any gross morbid lesions. It has been much disputed whether the increase in the dimensions of the organ is dependent on an increase in the size of the normal elements of the kidney, or whether it is dependent on an increase in their number. Experimental evidence has been adduced, more especially by Tuffier, to show that after removal of portions of the kidney new formation of renal elements takes place, and Tuffier considers that by progressive partial nephrectomies it is possible to remove an amount of kidney equal to the whole of that normally present, and yet for kidney-tissue to be found *post mortem*. This conclusion, however, has not been accepted by other authorities, and most observers are agreed that no such formation of new elements occurs after the removal of portions of one kidney. The removal of one kidney in animals or in man is usually, but not invariably, followed by a great increase in the size of its fellow; and in cases of congenital atrophy or want of development of one kidney, it is not uncommon for the other to more than equal the total weight and size of two normal kidneys. See KIDNEY, Atrophy of.

The removal of one kidney is more likely to be followed by an increase in size in the other when the organ is removed in the young. Unilateral extirpation of the kidney in old animals is not followed by any hypertrophic enlargement of its fellow, and it is well known that in cases of malignant disease in the human subject involving one kidney the opposite organ is frequently not enlarged. Most observers are agreed that in cases of so-called hypertrophy of the kidney the elements are somewhat enlarged. Hypertrophy of the kidneys in the human subject may involve one or both organs. Bilateral hypertrophy often occurs in diabetes mellitus, and, although in some cases of diabetes the kidneys present evidences of Bright's disease, it is not uncommon for both organs to be considerably enlarged without the presence of any other morbid lesion.

Unilateral hypertrophy, however, is much more common, and this is seen in cases of congenital absence of one organ, in cases of unilateral atrophy, and also as a result of unilateral disease. Where unilateral hypertrophy occurs it is not uncommon for the organ to be more than double the size and weight of two kidneys. The main importance of hypertrophy of the kidney, apart from its theoretical interest, rests in the fact that such a kidney may be mistaken for a renal tumour, and several instances are on record where an exploratory laparotomy has been done under this impression. Further, although the presence of a single hypertrophied kidney is compatible with prolonged life, many instances having been recorded in patients over eighty years of age, yet such kidneys often become involved in pathological processes, more especially calculous disease and Bright's disease. Calculous disease is especially formidable in such cases. Hypertrophy of the kidney as such produces no clinical symptoms.

KIDNEY, Inflammation of.—The term *nephritis* is sometimes applied to the initial stages of

Bright's disease and more especially to acute Bright's disease. It is better, however, to restrict it to the changes produced as a result of the action of certain specific poisons and more especially those produced during the height of certain infective diseases, such as scarlet fever, pneumonia, typhoid fever, and diphtheria. Three groups of renal poisons may be recognised. The first is represented by the action of cantharidin and probably by the virus of scarlet fever. The second consists of certain metallic salts. A third group consists of certain vegetable and animal toxic substances, such as abrin, ricin, serpent-venom, and bodies present in the blood of some animals, e.g. the eel. The first group produce their main effects on the glomeruli and give rise to what has been spoken of as a glomerulonephritis. The second group produce a coagulation-necrosis of the cells of the convoluted tubules. The organic poisons of the third group cause degeneration of the epithelial structures of the kidney differing in some respects from a coagulation-necrosis. In many respects the effects seen in nephritis are similar to changes produced in some stages of Bright's disease, and even to those seen in the more severe forms of acute congestion.

Bright's disease is looked upon by some as merely a more severe or more prolonged nephritis. The nephritis seen during the incidence of acute diseases may be described as transitory, and is the cause of the so-called febrile albuminuria seen during the height of these diseases. Some maladies that produce transitory nephritis during their height may lead to the production of Bright's disease later. Thus in pneumonia and scarlet fever transitory nephritis is very common during the height of the disease, and Bright's disease may arise during convalescence; but the two conditions do not necessarily merge into one another.

The transitory nephritis of these diseases is characterised clinically by a moderate and transient albuminuria unaccompanied by the more serious effects of Bright's disease, such as dropsy. In many cases it is probable that the lesions present in the kidney are scattered and partial in their distribution. In the more serious forms of nephritis seen as the result of the action of such poisons as cantharides or turpentine, hæmaturia and more or less complete suppression of urine may occur. In the great majority of cases the condition is temporary and the albuminuria soon subsides and the patient completely regains health. It is possible that in some such cases these forms of nephritis lay the foundation for permanent renal disease.

In the slighter forms no special treatment is called for, but in the more serious forms similar measures to those adopted in acute Bright's disease are required. *See* BRIGHT'S DISEASE.

KIDNEY, Inflammation of Pelvis of.—Pyelitis is an inflammation—acute or chronic—of the pelvis of the kidney. Pyelitis may exist by itself, or it may be part of a more widespread affection of the genito-urinary tract, such as cystitis on the one hand and suppuration of the kidney on the other hand.

ÆTIOLOGY.—Pyelitis may be caused by infection from the lower urinary tract, or by the irritation of toxic substances excreted by the kidney. It is possible that the infective agent may sometimes reach the pelvis of the kidney directly from the blood-stream without being excreted by the kidney.

In the great majority of instances, however, the infection reaches the pelvis of the kidney either from above or from below. Predisposing causes to pyelitis are afforded not only by the stagnation of urine in the renal pelvis as a result of obstruction caused by the presence of calculi, but also by dilatation of the ureter either of congenital origin or dependent on some former obstruction of the lower part. Dilatation of the ureter is a most important predisposing cause in cases of pyelitis dependent on infection from below. Pyelitis may complicate cystitis, as for instance in gonorrhœa, with little or no distension of the ureter; but it is in cases of enlarged prostate and urethral stricture complicated by dilatation of the bladder and ureters that pyelitis is most frequently seen (*see* KIDNEY, CONSECUTIVE INFLAMMATION OF). Micro-organisms are also excreted by the kidney, and in their passage down the urinary tract they may set up inflammatory mischief either in the kidney itself or in the pelvis; in this way a descending pyelitis may be produced. There are a number of acute diseases such as typhoid fever and acute pneumonia, in which slight pyelitis may be present, and a number of poisons, especially turpentine and cantharides, may cause pyelitis. Other causes of pyelitis are the presence of calculi and tubercular disease in the pelvis of the kidney. The majority of cases of pyelitis are the result of sepsis, calculi, or tubercular disease. It is said that exposure to cold may lead to pyelitis, but this is very doubtful.

MORBID ANATOMY.—The mucous membrane of the pelvis of the kidney is congested, coated with mucus, and often greyish in colour. Numerous punctiform submucous hæmorrhages are frequently present and may cause necrosis of the overlying epithelium and so produce ulcers. The renal pelvis may contain varying quantities of pus. If the disease is of any duration, the pelvis of the kidney will be dilated and its walls thickened, and, in some cases, covered by a kind of false membrane. In most cases, both the kidney and the ureter present marked changes, the latter being thickened and often dilated and its lumen more or less obstructed, partly by the swelling of the mucous membrane and partly by the accumulation of inflammatory products and blood. The changes in the kidney present considerable variety. In simple pyelitis little or no change is observed except that the apices of the renal pyramids may be somewhat flattened. The pyelitis is frequently complicated by the presence of pyelonephritis or by pyonephrosis; in the former case areas of suppuration of varying size are found extending between the pyramids of the kidney into the cortex, and there are often numerous small abscesses in the cortex beneath the capsule. In pyonephrosis the kidney undergoes distension similar to that seen in hydronephrosis, but the renal tissue presents many inflammatory changes. The distension may be so great that the organ remains simply as a bag containing pus. In other cases where the distension is not so great, areas of the medullary portion of the kidney, more or less considerable in size, show necrotic changes. When pyonephrosis ensues as a complication to pyelitis, the capsule of the kidney is often greatly thickened, and adhesions may be formed between the kidney and surrounding organs.

SYMPTOMS.—The symptoms produced by pyelitis depend not only on the severity of the disease, but also very largely on its cause. In simple pyelitis, unassociated with the presence of calculi or

local tuberculosis, pain of moderate severity is felt in the loin; but in many cases this is not sufficiently severe to be called more than uneasiness. Frequency of micturition is often present, and a marked feature even when there is no evidence of the presence of cystitis. The urine is acid, and contains a variable amount of pus. Hæmaturia is not generally a marked feature, unless the pyelitis is due to local irritation (calculi or tuberculosis). The amount of albumen in the urine is small, and is dependent on the presence of the pus. Albuminuria out of proportion to the quantity of pus present is a sign of the involvement of the kidneys by some other morbid process, most commonly amyloid disease. Fever is usually present, and its course exceedingly irregular. In the more severe forms the temperature may be high and rigors may occur; while attacks simulating those of renal colic may be produced by the dislodgment of inflammatory products and by the passage of blood-clots through the ureter. There is usually tenderness on deep pressure over the affected kidney. When pyonephrosis ensues the urine frequently remains free from pus, since the production of the pyonephrosis involves the obstruction of the ureter. Where pyelonephritis is present as a complication or accompaniment of pyelitis the patients are much more profoundly ill; they become wasted, and assume a cachectic appearance and suffer from hectic fever. Where pyonephrosis develops, the tumour formed by the distended kidney may often be recognised. Pyelitis may be unilateral or bilateral. The former is seen in some cases of calculus and tubercular pyelitis, the latter more often where the pyelitis is a sequel of cystitis. In calculous pyelitis pain is a more prominent feature than in the simple variety, and such patients often present a history of the passage of calculi or gravel. Hæmorrhage is also often profuse in cases due to calculi. In tubercular pyelitis the discharge of pus is usually abundant and that of blood scanty, although cases have been described in which the onset of tubercular pyelitis was marked by profuse hæmaturia. In tubercular pyelitis tubercle-bacilli may be found in the urine, either by microscopical examination of the centrifuged deposit, or else by the inoculation of susceptible animals with the suspected urine. The latter is on the whole the more reliable method, owing to the difficulties occasionally experienced in distinguishing between the *Bacillus tuberculosis* and the *smegma-bacillus*.

DIAGNOSIS.—The diagnosis of pyelitis is usually readily made in uncomplicated cases by examination of the urine. Some difficulty may be experienced in determining whether the disease is unilateral or bilateral, and most frequently this has to be determined by the situation of the pain and tenderness. In some cases, and more especially in the female, cystoscopic examination of the bladder and catheterisation of the ureters may afford certain evidence as to the situation of the disease. Difficulties sometimes present themselves in distinguishing between cystitis and pyelitis, since, although the urine is generally alkaline in cases of cystitis and acid in pyelitis, this is not invariable, and some forms of cystitis occur with acid urine, and pyelitis complicating cystitis may be accompanied by an alkaline urine. The diagnosis has usually to be based on the presence of renal pain and tenderness. It is often a matter of great importance to determine whether pyelonephritis is present. Where this is the case the patient is usually more ill, more

wasted, and suffers from more characteristic hectic fever than where pyelitis alone is present. The urine in pyelonephritis is often abundant and of low specific gravity. Calculous is to be distinguished from tubercular pyelitis by the history, by the greater tendency to hæmaturia, and often by its longer duration. Calculous pyelitis is a malady which may exist for many years without seriously interfering with the general health. The most reliable means, however, of distinguishing between the two is by determining the presence or absence of tubercle-bacilli in the urine.

PROGNOSIS.—The prognosis of pyelitis depends on its cause. In the slighter forms dependent on the presence of gravel this is not unfavourable. The trivial pyelitis accompanying acute specific fevers is also of no great importance, except that it may lay the foundation for subsequent calculous disease. Cases of septic pyelitis and of tubercular pyelitis are grave. Pyelitis complicating gonorrhœa may even be fatal by setting up pyæmia; but many of these septic varieties of pyelitis can be successfully treated by operative interference.

TREATMENT.—Many forms of pyelitis require surgical treatment, such as the removal of stones or the draining of the distended kidney, or even in some cases the passage of a long catheter up the ureter and the washing out of the renal pelvis. The slighter forms associated with the presence of gravel may often be greatly benefited by medical treatment. The diet should be light, and all stimulating drinks should be avoided. The patient should take large quantities of barley-water, of infusion of buchu, or of linseed-tea. Alkalis, such as carbonate or citrate of potassium, often relieve the urgency of micturition; and *uva ursi* and infusion of buchu have been recommended for the same purpose. Mild counter-irritation may be applied to the loins to relieve the pain.

KIDNEY, Malpositions of.—Malpositions may be congenital or acquired. Further, the kidney may be fixed in its anomalous position, or the displacement may be accompanied by mobility. The most important congenital malpositions of the kidney are those in which the organ is situated (1) over the sacro-iliac synchondrosis; (2) in the concavity of the sacrum; or (3) in the iliac fossa. Such displacements usually involve only one kidney. Malposition of the kidney is often associated with other congenital anomalies, especially with anomalies in the development of the large intestine, and in its relation to the peritoneum. In some instances imperforate anus is associated with malposition of the kidney. The most frequent of the 'fixed' displacements is that over the sacro-iliac synchondrosis. A fixed displacement of the kidney is of some clinical importance, since (1) it may be mistaken for a tumour, as in the case of a kidney occupying the concavity of the sacrum and palpable *per rectum*; and (2) the displaced organ may become enlarged and tender, as a result of kinking of the renal vein. In this way considerable pain may be produced, and the condition be erroneously diagnosed as inflammatory, as in a case in which a swollen kidney, situated in the iliac fossa, was diagnosed as inflammation of the appendix.

Displacements with mobility are usually known as *movable kidney*. Two varieties of movable kidney are generally recognised: one where the mobility of the organ is slightly greater than normal,

so that it descends more during the normal respiratory movements; the other, where the unnatural mobility is far greater, so that the organ can be moved about freely in the abdominal cavity; to the latter variety the name of floating kidney has sometimes been applied. The normal kidneys move considerably during respiration, but not to an extent sufficient to allow the hand to be inserted above the kidney. Some authorities consider that if more than the lower third can be felt during inspiration the term 'movable kidney' should be applied to the condition. In the slighter forms of movable kidney the organ maintains its normal relations to the peritoneum, but in the more severe forms, or 'floating kidney,' the peritoneum passes behind the kidney to a variable extent, forming a kind of mesonephros. It is probable that the formation of this spurious mesonephros is generally congenital, but it may also be acquired as a result of unnatural mobility of the organ. The kidney normally is kept in its position partly by the pressure of the adjacent viscera and the tonic contraction of the abdominal muscles. In addition to these the most important factors are the bands of fibrous tissue which pass through the fatty bed in which the kidney lies, and also the reflections of the peritoneum from the kidney to the adjacent organs. The most important of the latter is the reflection passing from the anterior surface of the kidney to the duodenum.

ÆTIOLOGY.—Movable kidney is more common in women than in men, and the right kidney is more frequently affected than the left. The slighter forms of movable kidney are extremely prevalent in women, but such a condition apart from the production of symptoms is scarcely to be looked upon as pathological. Predisposing causes are distension of the abdomen and laxity of the abdominal walls, arising either as a result of the distension, or else due to impaired nutrition. In some instances the condition has developed as a result of tight-lacing. In many it has followed traumatism, either direct injury to the loin or more often displacement of the organ resulting from a shock or jar produced by jumping.

MORBID ANATOMY.—The kidney may be found in its normal situation, but owing to looseness of attachments it may be more freely movable behind the peritoneum. In the more serious forms the spurious mesonephros will allow the kidney to be moved about freely in the abdominal cavity. The kidney itself does not usually present any marked changes, but in some instances of extreme mobility where kinking of the vein or of the ureter has resulted, the results of these conditions may be visible (see **HYDRONEPHROSIS**; and **KIDNEY**, Congestion of). In some cases, changes in other organs are found, e.g. dilatation of the stomach, which apparently is produced by the traction exerted on the duodenum by the displaced organ through the peritoneal reflections passing from the kidney to the duodenum. The common bile-duct may also be dragged upon and partially obstructed in this way.

SYMPTOMS.—In a large number of cases no symptoms are produced, and the condition is recognised accidentally during examination of the abdomen for other purposes. In a certain number of cases, however, the patients seek advice with more or less characteristic symptoms, and in a small proportion of cases the effects produced may be severe. One of the most constant symptoms is

pain in the abdomen and loin, which occasionally resembles that of renal colic. In these cases, there may be nausea and vomiting with tenderness in the abdomen and loin. Abdominal distension may occur, and intestinal obstruction be simulated. Neurasthenic symptoms are often present even in cases where the pain and other effects produced are not severe, and instances occur in which no other signs than those of movable kidney are seen in patients suffering from very severe neurasthenia. In such cases wasting is often a marked phenomenon. In a small proportion of cases of movable kidney, hæmaturia occurs, accompanied by severe pain, and it is supposed that in such cases kinking of the renal vein has resulted from the unnatural mobility of the organ. Transient jaundice is rarely met with; gastric symptoms are accounted for by dilatation of the stomach. Intermittent hydronephrosis is one of the most important of the more serious effects produced by this condition.

DIAGNOSIS.—The condition is usually readily recognised owing to the fact that a large number of patients suffering from it are emaciated and palpation of the abdomen readily reveals the extreme mobility of the organ. Pressure on the kidney often causes nausea and faintness. The condition may be overlooked where the patient presents only gastric symptoms, and difficulties may arise in the differential diagnosis between some forms of movable kidney and calculus, as both may produce paroxysmal pain and hæmaturia. Although neurasthenia is often associated with movable kidney, the latter is not often the sole cause of the former, and the neurasthenia may persist in all its severity after the successful relief of the movable kidney.

PROGNOSIS.—In the vast majority of cases the condition is not serious, but the pain may be of sufficient severity to interfere with the normal avocations of the patient. Where hydronephrosis is produced more or less serious effects may result.

TREATMENT.—When no symptoms are present no treatment is required. When symptoms are present, relief can, in the majority of cases, be given by the application of a suitable belt or pad, and by measures directed to the improvement of the general health, and especially the tone of the abdominal muscles. Massage and Weir-Mitchell treatment may be of service, but massage is sometimes harmful, and the mobility increased by it. Surgical treatment may be required if the pain be severe and constant, especially if hydronephrosis have resulted. In such cases nephrotomy, nephrorrhaphy or even nephrectomy may be required.

KIDNEY, Morbid Growths of.—Both simple and malignant growths occur in the kidney. The former are of no great clinical importance and include adenomata, fibromata, lipomata, angiomata, and myxomata. In addition to these, gummata, and the growths peculiar to leucocythæmia and lymphadenoma, are not uncommon.

Adenoma is the most common simple growth affecting the kidney, and is usually no larger than a split pea. It may be found in healthy kidneys, but more often in granular kidneys. In some instances it may reach a large size and may be bilateral. An isolated fibroma is sometimes seen in the medullary portion of the kidney, and in rare instances multiple fibromata occur in the capsule

associated with fibromata in other parts, especially the ovary.

The malignant growths commonly affecting the kidney are sarcoma, carcinoma, and malignant adenoma. In addition to these, columnar epithelioma is met with, and even squamous epithelioma, occurring as a primary growth, has been described.

Renal sarcomata are usually of the round- or spindle-celled variety; in a few rare instances alveolar sarcoma has occurred. Sarcomata are met with most frequently in early life, and in a considerable number of the cases the tumour contains striated muscle-fibres; to these malignant sarcomatous tumours the name of rhabdomyoma has been applied. This form of tumour is common in cases of congenital sarcoma, but is also met with in sarcoma occurring in young children. Melanotic sarcoma in the form of secondary growths also occurs in the kidney, and may be accompanied by melanuria. *See* PIGMENTATION; and URINE, Morbid Conditions of.

In most cases of carcinomata affecting the kidney the growth is of the encephaloid variety; scirrhus is only rarely met with. In many instances the encephaloid growth undergoes colloid or other form of degeneration; the growth is usually exceedingly soft and friable.

In a considerable proportion of cases of malignant diseases of the kidney the growth really begins in what is spoken of as a suprarenal 'rest.' These 'rests' are situated in the cortex of the kidney beneath the capsule, and the growths arising in them resemble in their structure that of a suprarenal body, but, owing to the presence of considerable quantities of fat, this may be overlooked. These growths often reach a considerable size, and they may either infiltrate or compress the neighbouring substance of the kidney. These tumours are accompanied by secondary growths, similar in structure, in other parts of the body. The structure of a growth arising from a suprarenal 'rest' resembles that of malignant adenoma more than that of sarcoma. In many cases its clinical course is relatively slow.

Villous tumours of the mucous membrane of the calices and of the renal pelvis sometimes occur, and may reach a very large size.

In about half the cases of malignant growths involving the kidney, the tumour remains confined within the capsule of the organ, even when the growth has reached a very large size; and in this way a more or less general enlargement of the kidney is produced. In the rest of the cases the growth perforates the capsule. The growth often spreads along the renal vein and may produce thrombosis of this vein or of the vena cava. Secondary deposits occur, especially in the lungs, the liver, and in the lumbar glands.

SYMPTOMS.—The more benign tumours of the kidney usually give rise to no symptoms. Cases of adenoma of the kidney have been described in which, owing to extensive cystic degeneration of the growth, effects have been produced resembling both clinically and histologically those seen in cystic disease of the kidney.

Pain, hæmaturia, and the presence of a tumour form the characteristic clinical features of malignant disease of the kidney. The pain is usually felt in the loin, and is liable to undergo exacerbations simulating those of renal colic. In some cases these attacks of pain are dependent on the passage of blood-clot or of fragments of the growth.

Hæmaturia occurs in about one half the cases and may be very profuse; it is usually intermittent. In rare instances fragments of the growth have been detected in the urine. In most cases a renal tumour can be detected, and presents the usual features. It is not unusual for the tumour to be of sufficient size to be visible through the abdominal parietes, and in such cases the superficial veins of the abdomen may be unnaturally distended owing to the interference with the circulation through the vena cava. The tumour presents the ordinary features of a renal tumour. It is limited to one side of the abdomen, has a rounded outline, and moves but slightly with respiration. The presence of the colon crossing the tumour can often be determined either by palpation or by percussion. When the disease is fully established, the characteristic asthenia and cachexia are produced especially in the case of carcinoma. Intestinal obstruction may result from pressure on the colon or from the growth invading some portion of the intestine. In rare instances the disease may spread and involve the vertebral column and produce paraplegia. Thrombosis of the vena cava may lead to œdema of the legs. Ascites may also occur if the peritoneum be invaded.

DIAGNOSIS.—The diagnosis is usually based on the presence of a renal tumour together with hæmaturia and in many cases cachexia. If hæmaturia is absent, the renal tumour may be mistaken for a splenic tumour, for enlarged abdominal glands, for perinephric abscess, or for certain tumours of the liver and ovary. Splenic tumours usually present a sharp edge and notch, and are more movable with respiration than renal tumours; and it is exceptional for the colon to pass in front of a splenic tumour. In some cases a splenic tumour is vertical instead of oblique, and then the difficulty of distinguishing between the two is greater. Even when both hæmaturia and a renal tumour are present, errors may be made, as in one instance where hæmorrhage occurred into the sac of a hydro-nephrotic kidney, producing a solid renal tumour and hæmaturia. Where a tumour cannot be felt the difficulties are considerably greater, as profuse hæmorrhage like that seen in malignant disease may occur with renal calculus and renal tuberculosis, and even in some cases of granular kidney. *See* PHYSICAL EXAMINATION.

PROGNOSIS.—The average duration of carcinoma of the kidney is a year, but in exceptional cases life may be prolonged for several years. In sarcoma the course of the disease is still more rapid.

TREATMENT.—Medical treatment is purely palliative. Morphine is given to relieve the pain. The bowels require especial attention owing to the constipation resulting from the pressure on the descending colon.

If the tumour has its origin in a suprarenal 'rest,' surgical interference is often successful; the removal of the whole kidney is not always necessary, for, in some cases, the growth can be shelled out.

In cases of carcinoma and sarcoma the prospects of a cure by nephrectomy are not so favourable. The results of removal of sarcoma are rather better than those of carcinoma, but recurrence is frequent.

Owing to the doubt that must exist in a large number of cases as to the actual nature of the morbid growth present, an exploratory laparotomy is generally advisable.

KIDNEY, Parasites of.—The parasites which have been described as existing in the human kidneys are hydatids (*see* p. 831). *Strongylus gigas*, *Pentastoma denticulatum*, *Bilharzia hæmatobia*; also the larval form of the *Filaria sanguinis hominis*, which inhabits the lymphatic vessels, either of the kidneys themselves, or of some lower part of the urinary tract.

TREATMENT.—In the treatment of patients affected with *Bilharzia hæmatobia*, the internal use of oil of turpentine is recommended. It is stated that, when the bladder is affected, vesical injections of iodide of potassium, twenty or thirty grains dissolved in tepid water, repeated every second or third day, have been found useful. *See* ENTOZOA; CHYLURIA; and KIDNEY, Hydatid-Disease of.

KIDNEY, Syphilitic Affections of.—Syphilis, like other acute specific diseases, may cause or predispose to certain affections of the kidney. Bright's disease is not uncommon as a complication during the early stages of syphilis. In this respect the influence of syphilis is comparable to that of scarlet fever and other acute diseases, since it may not only lead to the production of Bright's disease, but may also produce a transient albuminuria. When Bright's disease ensues as a sequel to syphilitic infection, the disease runs the same course as when due to other causes. Amyloid degeneration of the kidney is a common result of syphilis, and is sometimes erroneously diagnosed as Bright's disease (*see* BRIGHT'S DISEASE). In rare instances gummata are formed in the kidney, but there is no means of diagnosing their presence.

KIDNEY, Thrombosis of.—Thrombosis of the renal vessels is a rare lesion: venous thrombosis is more frequent than arterial. Thrombosis of the renal vein may occur primarily during the course of debilitating diseases, e.g. diphtheria. It is more usual as a result of extension into the renal veins of thrombi arising in the inferior vena cava. In such cases the thrombosis may start in the veins of the pelvis or of the lower limb, and may gradually involve the vena cava until it reaches the point of entry of the renal veins. Such renal thrombosis is seen in cases of primary septic pelvic diseases, after operations such as ovariectomy or the removal of uterine 'fibroids,' or following the septic complications of childbirth. In rare instances thrombosis spreading from the pelvic veins to the vena cava and renal veins is seen after abdominal operations involving the ligature of pelvic veins without any clear evidence of the presence of septic complications. Thrombosis of the renal veins may also complicate certain renal diseases, especially malignant disease of the kidney and granular contracted kidney. Thrombosis of the renal veins leads to extreme passive congestion of the kidneys and, if bilateral, to complete suppression of urine; but in many instances only one renal vein is involved.

Thrombosis of the renal artery or its branches occurs in very rare instances as a result of the presence of endarteritis. In such cases effects very similar to those seen in embolism are produced, more or less extensive areas of the cortex of the kidney undergoing necrosis. In one instance, recorded by the writer, bilateral thrombosis of the interlobular arteries occurred, producing complete necrosis of the cortex of both kidneys.

KIDNEY, Tuberculosis of.—Renal tuberculosis exists in two forms. (1) In one the organ contains scattered miliary tubercles, and the renal infection is part of a general tuberculosis. In such cases the renal lesion does not develop to any great extent, and the tubercles are always of small size. They are most abundant in the cortex in the vicinity of the capsule, and are usually of a yellow tint. A few scattered tubercles may be found in the medulla. In exceptional instances the individual foci may reach the size of a split pea. In this form of the disease the infecting agent reaches the kidney through the blood-stream, and the bacilli are arrested in the capillary tufts and in the interstitial tissue between the tubules. Bacilli may be present in the urine in small numbers. Miliary tuberculosis of the kidney produces no symptoms, and is of no clinical importance, the lesions in other parts, especially in the lungs and meninges, overshadowing those in the kidney.

(2) In the other form of tuberculosis of the kidney the disease is more localised, but the tubercular foci are more extensive. One or both kidneys may be involved, and no other organ may be affected. More frequently, however, the local tuberculosis is associated with similar disease in other parts of the body, especially of the genito-urinary tract. This is peculiarly the case in males; the epididymis, bladder, vesiculæ seminales, and prostate being most frequently involved. It is to this form of the malady that the expression tuberculous kidney is generally applied.

ÆTIOLOGY.—Tubercular disease of the kidney is more common in children and young people, but many instances are met with in the earlier years of adult life, and the disease is more common in men than in women. In tubercular disease of the genito-urinary tract it is rare for the lower portion of the tract to be alone affected; and, for this among other reasons, it is probable that in many cases the tubercular infection of the kidney is primary, and the involvement of the lower urinary tract, such as the bladder or prostate or ureter, is secondary. In a certain proportion of cases variously estimated by different authorities, the renal lesion is consecutive to a primary focus of tuberculosis in the prostate, epididymis, or some other part of the genito-urinary tract. In some instances the malady spreads by direct continuity from the bladder to the kidney along the ureter, the latter being thickened along its whole course, and its mucous membrane ulcerated. In other cases it would seem that the infection reaches the kidney from the lower urinary tract in a similar manner to that seen in pyelonephritis, namely by the lymphatics. All writers are agreed that in a certain proportion of cases, estimated by some to be as high as 40 per cent., the renal lesion in cases of tuberculosis of the genito-urinary tract is the primary one. For these reasons the co-existence of tubercular lesions in the kidney and genito-urinary tract is frequent.

MORBID ANATOMY.—The renal lesions in tuberculous kidney are very various. In most instances extensive areas undergoing caseation are found in the cortex of the organ involving the medulla by direct extension. These masses are somewhat conical in section and roughly resemble infarcts. The caseation that the central parts undergo leads to the formation of cavities with shreddy walls. The number and size of these areas present great variation. Their contents may undergo calcifica-

tion. In most instances the mucous membrane of the pelvis of the kidney is also affected and contains tubercles. As a result of their caseation, ulcers of varying size are formed. The pelvic mucous membrane generally is greatly thickened, and this may be sufficient in amount to cause obstruction to the exit of urine, and thus lead to the formation of a pyonephrosis. The ureter may also become blocked by the detachment of fragments of the tuberculous tissue, or in some instances by the thickening produced by tubercular changes in its wall at some distance from the pelvis of the kidney. In this way also a hydro- or pyonephrosis may be produced. Occasionally fibroid changes take place, leading to the atrophy of the kidney and the encapsulation of the tuberculous tissue contained in it. Even where the disease is primary in the kidney, other organs soon become affected, such as the abdominal glands, the lungs, and occasionally the intestines.

SYMPTOMS.—The deposit of tubercle in the kidney may lead to moderate enlargement of the organ quite apart from the development of such complications as pyo- or hydronephrosis, and in such instances a renal tumour may be detected. More often the enlargement of the kidney is slight in amount, and on palpation pain and tenderness are more frequently detected than the presence of any notable enlargement of the organ. The symptoms of pyelitis are usually present, owing to the frequency with which the tubercular changes involve the renal pelvis. The symptoms of tubercular pyelitis resemble in many respects those of calculous pyelitis; but the frequency of micturition is often extreme, and not so definitely related to movement. Thus it may be quite as marked by night as by day. Pain is commonly present, and is usually constant in the lumbar region. Exacerbations may occur from time to time which may be due to the temporary blocking of the ureter by fragments of the tuberculous tissue. Pus in variable amount is present in the urine. The amount of albumen is usually related to the quantity of pus present, but it is not uncommon for amyloid disease of the kidney to exist as a complication, and in such cases the albuminuria is greater. Hematuria is often present during some period of the illness, and is usually scanty in amount; but it is not very exceptional for profuse hematuria to occur from time to time. The general effects that are usually seen in tuberculosis of other organs, such as emaciation, sweating, and pyrexia, are commonly present. Examination of the urine will frequently reveal the presence of tubercle-bacilli, and their presence may not only be detected by the ordinary methods of staining, but also by the inoculation of susceptible animals with the suspected urine. In cases of doubt the latter is the better procedure, as difficulties are sometimes experienced in distinguishing with accuracy between the *Bacillus tuberculosis* and the *Smegma-bacillus*. Death may be due to uræmia, or sometimes to suppression of urine; but in a large proportion of cases it is dependent on the extension of the disease to other parts, more especially the lungs and the intestine.

DIAGNOSIS.—In most instances the disease will present itself with the symptoms of pyelitis, and the diagnosis may be made by the detection of the bacilli in the urine, or by the evidence of tuberculosis of the genito-urinary tract, such as the epididymis, prostate, and, in women, the thickening of the ureter. In cases where blocking of the ureter

has led to distension of the kidney some difficulty may be experienced in distinguishing between simple pyonephrosis and one complicating tubercular disease.

PROGNOSIS.—The prognosis is very grave, although where the disease is strictly unilateral success has followed the removal of the affected kidney. Catheterisation of the ureters may afford useful evidence as to the presence of unilateral disease. Where the malady is fully established, life is not usually prolonged for more than a few months; but cases have been known to live as long as three years after the nature of the disease has been recognised.

TREATMENT.—Where there is clear evidence of the disease being limited to one kidney nephrectomy is advisable, but in other cases treatment can only be directed to the relief of the pain and the promotion of the general health, such as are employed in the treatment of tuberculosis elsewhere.

JOHN ROSE BRADFORD.

KINÆSTHESIS (κινέω, I move; and αἴσθησις, sensation).—The sense by which we appreciate the character and extent of voluntary movements.

KINETOPLASMA.—The granules in a motor-cell which are stained by basic dyes, and often known as a chromophile or chromatic substance.

KING'S EVIL.—A popular name for scrofula, originating in a belief formerly held that the disease could be cured by the king's touch. See SCROFULA.

KISSINGEN, in Bavaria.—Common salt waters. See MINERAL WATERS.

KLEBS-LÖFFLER BACILLUS.—A synonym for the *Bacillus diphtheriæ*. See DIPHTHERIA.

KLEPTOMANIA.—Insanity characterised by an irresistible impulse to steal. See INSANITY, Impulsive; and CRIME, Irresponsibility for.

KOPF-TETANUS.—A local manifestation of tetanus occurring in cases in which the face is injured, and attended by trismus and facial paralysis. Later on the general phenomena of the disease supervene.

KOPLIK'S SPOTS.—Small red spots, with pale blue centres, sometimes observed on the mucous membrane of the mouth during the pre-eruptive stage of measles. See MEASLES.

KRA-KRA.—SYNON.: *Craw-craw*.—A word used by negroes to denote any form of skin-eruption characterised by much local inflammation, and especially by the presence of pustules.

KRAUROSIS (κραῖρος, dry).—An atrophic condition of the female generative organs, accompanied by intense itching of the affected parts.

KREUZNACH, in Germany.—Common salt waters containing iodine. See MINERAL WATERS.

KROUOMANIA (κρούω, I shake).—This term is sometimes applied to co-ordinated movements, rhythmically repeated, and found principally in 'habit-spasms' in feeble-minded children.

KYPHOSIS (κυφός, bent).—A synonym for angular deformity of the spine. See SPINE, Diseases of.

L

LABIO-GLOSSO-LARYNGEAL PARALYSIS

(*labium*, a lip; *γλῶσσα*, the tongue; and *λάρυγξ*, the throat).—There are two forms of this disease, which have to be considered separately, namely (A) a **chronic** form; and (B) a **sudden** form—the latter is often termed ‘acute,’ but is, as a rule, sudden in onset. (C) A true **acute** (not sudden) variety is met with in rare instances. A fourth variety, **pseudo-bulbar** paralysis, entirely different in seat, needs to be distinguished, but will be afterwards described.

(A) **Chronic Labio - Glosso - Laryngeal Paralysis.**—SYNON.: Bulbar Palsy; Duchenne's Paralysis; Fr. *Paralysie Glosso-labio-laryngée*; Ger. *Progressive Bulbarparalyse*.

DEFINITION.—A progressive symmetrical paralysis of the lips and adjacent facial muscles, of the tongue, pharynx, and sometimes also of the larynx; with or without conspicuous wasting; and often associated with muscular atrophy elsewhere.

ETIOLOGY.—Of the causes of the affection little is known. It is a disease of later life, being almost unknown under forty. Exceptional cases have been met with in early adult life, and even in late childhood. In the latter instances several members of a family have been known to suffer, and a congenital tendency to early failure of vitality in the structures concerned may reasonably be assumed. In the common form, males are affected more frequently than females. The disease, as such, does not appear to be inherited, but in many cases there is a family history of other affections of the central nervous system. Of immediate causes, exposure to cold, mental anxiety, and defective nourishment have been supposed to exert an influence.

ANATOMICAL CHARACTERS.—When, as is commonly the case, there is wasting of the paralysed parts, their muscles are reduced in size, and present changes similar to those met with in the limbs in chronic spinal atrophy. Their substance is pale; fatty tissue may be in excess; and the muscular fibres often, but not always, present granular degeneration. They are frequently narrowed, and the tissue between them may be increased in quantity, and may contain pigmentary and other products of degeneration, and an increased number of nuclei. When there is no apparent wasting, this may be merely because the interstitial fat is increased so as to compensate for the reduction in bulk of the muscular fibres. Rarely the structure of the muscles presents little alteration. The motor nerve-fibres are grey, translucent, and, under the microscope, degenerated. Their nuclei of origin in the medulla oblongata are also diseased. The motor cells are shrunken and atrophied; their processes are lost; and the intermediate tissue is degenerated. The hypoglossal nucleus is examined most readily, and the change in it is striking, as well as in the nucleus of the spinal accessory (palate and larynx); changes may often also be seen in the nuclei of the glosso-pharyngeal, the vagus, and the ‘nucleus ambiguus.’ The anatomical alteration which underlies the affection of the lips has not yet been detected. There is still uncertainty regarding the precise origin of this part of the facial nerve. Most of its fibres diverge from the middle line, close

to which the hypoglossal nucleus is situated, and some at least pass towards the lower part of the column of cells, which, above, gives origin to the motor fibres of the fifth nerve. It is certain, however, that many fibres of the facial descend towards the level of the hypoglossal nucleus. Further, the physiological association of the movements of the tongue and lips is most close. We cannot narrow the tongue without contracting the orbicularis. Hence it is certain that the nucleus for the lower facial muscles and the hypoglossal nucleus, whether blended, contiguous, or distant, are closely connected and are alike predisposed to disease, so that this connected part of the facial nerve suffers in the same manner as the hypoglossal. In the same manner the fibres for the orbicularis palpebrarum suffer with those for the ocular muscles. The fibres passing to the nuclei from the cerebral hemispheres may also be degenerated, and it is probable that these are alone affected in the cases in which there is no wasting in the muscles. When there is muscular atrophy in the limbs, a corresponding degeneration may be found in the anterior cornua of the spinal cord, often conjoined with sclerosis in the lateral columns, and in the anterior pyramids in the medulla. There is every reason to believe that, in the chronic form, the atrophic changes in the nerve-elements are the primary alteration.

In very rare cases, no morbid appearance has been observed in the medulla. Some of these may have been cases of peripheral neuritis, local and degenerative. In others, in which even the nerve-endings were normal, the degeneration of cerebro-nuclear fibres may have escaped observation, or some toxic influence may have abolished function without causing destructive degeneration.

SYMPTOMS.—The symptoms have the distribution indicated by the name given to the disease by Trousseau, the affected parts being the lips, tongue, throat, and larynx. They are, so to speak, arranged about the tongue as a centre. It is in this organ that the earliest symptoms commonly present themselves, as a trifling indistinctness of speech, due to an imperfect articulation of those sounds in which the tongue is most concerned—especially the dental and palatine explosive sounds, in which the tongue has to be pressed against the teeth or hard palate, *t, d, k, g* (hard), &c. The tongue can be still protruded, although perhaps not quite so far as normal. The lips then become weak, and sounds in which the lips are concerned are imperfectly articulated. The vowels *o* and *oo*, in the pronunciation of which the orbicularis contracts so as to protrude the lips, cannot be well sounded. The lips are not brought together so perfectly, or separated so promptly, as in health, and the labial explosives, *b* and *p*, become *f*, and so does the labial resonant *m*. Whistling is impossible. The lower part of the face loses its expression, the lips are habitually separated, and the saliva cannot be perfectly retained. The difficulty in articulation is soon increased by the weakness of the palate, which ceases to shut off the nasal cavity, so that a nasal resonance accompanies sounds from which it should be absent. The paralysis of the tongue increases until the organ can no longer be protruded. Deglutition becomes impaired, partly

from the weakness of the tongue, but in part also from that of the constrictors of the pharynx. The soft palate ultimately hangs motionless, or, if it can be raised a little in an attempt to phonate, during the act of swallowing does not close the posterior nares, so that liquids regurgitate into the nose. Food is apt to lodge in the upper part of the pharynx, and crumbs or liquid to get into the larynx. The laryngeal muscles subsequently become weak, and the glottis cannot be closed. The vocal cords may be equally affected, or one may be paralysed in greater degree than the other. Coughing is necessarily imperfect: air is driven through the larynx, but there is no sudden opening of a previously closed glottis, and hence no explosive cough. In proportion as the glottis is paralysed, phonation is interfered with, but the ability to produce some sound is rarely altogether lost. As the disease progresses, the speech becomes almost unintelligible, being reduced to unarticulated and scarcely modulated vocal sound. It is to be noted, however, that for a long time the habitual articulation is rarely the best possible. Words can be distinctly articulated by a deliberate effort which are scarcely at all articulated in ordinary speech. The saliva can neither be swallowed nor retained within the mouth, and is constantly dribbling over the lower lip, below which the patient has to hold a handkerchief continually. It has been thought that the quantity of saliva is increased, but the evidence of this is insufficient. The condition of the tongue varies much in different cases. In some it is large, broad, flabby, and soft to the touch throughout. In others it is conspicuously wasted, and covered with wrinkles and furrows from the shrinking. In some cases the lips retain their normal size; in others they are distinctly thinner than normal. This striking contrast between different cases (already referred to) led Duchenne to distinguish two varieties, the *atrophic* and the *paralytic*, but in some of the cases of the latter class it is merely the increased interstitial fat that prevents wasting from being conspicuous during life. In the affected muscles the electrical irritability is usually little changed: they still contract to the faradic current, even when the atrophy is conspicuous. Sometimes there is an indication of the reaction of degeneration, in undue readiness of contraction to the anodal (positive) closure, or this reaction may be well marked, faradic irritability being much lessened. Other muscles of the head are rarely affected. Those in the upper part of the face always escape, and the zygomatic muscles, with the elevators of the upper lip, are so little affected that their unopposed contracture produces a peculiarly deep and characteristic naso-labial furrow. In many cases muscular atrophy in the limbs, in greater or less degree, is associated. So, too, in cases of ordinary muscular atrophy, commencing in the limbs, the lips, tongue, and throat are often affected towards the end of the case, in the same manner as in the primary form, but in less degree.

Death, in labio-glossal paralysis, is usually the result of asthenia, due, it may be, in part, to the difficulty in deglutition, or it is the result of chronic lung-disease produced by the repeated entrance of particles of food into the air-passages. Sometimes the patient dies in a paroxysm of coughing, occasioned by an ineffectual attempt to swallow liquids or saliva.

DIAGNOSIS.—Before labio-glossal paralysis was well known, the difficulty in swallowing was as-

cribed to a chronic inflammation of the fauces, but this mistake is now scarcely possible. Yet the writer has known it to be mistaken for cancer of the throat. The symptoms have to be distinguished from those due to other diseases of the medulla, and to disease elsewhere. Many sudden lesions, in the region affected in this disease, may cause similar symptoms, but these are distinguished by their onset. Compression of the medulla may also give rise to symptoms of similar distribution, but these are commonly unilateral, or one side suffers before, and more than, the other; and they are often accompanied by a preponderant affection of the muscular part of the spinal accessory nerve, and by great weakness, without wasting, in the limbs. In 'pseudo-bulbar paralysis,' movements of the tongue are impaired by disease of the cerebral hemispheres. These movements are represented in the lower part of each ascending frontal convolution. When this region is diseased on one side, the loss is soon compensated for by the centre in the opposite hemisphere, but a symmetrical bilateral lesion in this situation may cause complete paralysis of the tongue and other parts affected in the disease now described. Such paralysis is acute in onset so far as its complete degree is concerned, and therefore is chiefly liable to be mistaken for the sudden form, presently to be described.

PROGNOSIS.—The prognosis is always grave. The chronic disease consists in a slow degeneration of the nerve-elements, the effects of which often lead to death in about a year from the onset. Although, in some cases, a temporary arrest may be obtained, and occasionally the malady, after causing a considerable degree of disability, is arrested for several years, it is doubtful whether, in any instance of this form, definite improvement has been produced. The prospect of prolongation of the state of arrest, if this occurs, depends very much on the amount of care the patient can secure. The older the patient, the less is the likelihood of arrest.

TREATMENT.—The degenerative tendency which underlies chronic labio-glossal-laryngeal paralysis is usually beyond the reach of remedies. It is essentially a senile failure of nutrition, local and premature, and as little amenable as are other manifestations of senile decay. Therapeutical efforts must be chiefly directed to the endeavour to retard it, by securing freedom from any cause that can be traced, especially from depressing emotion, overwork and the like, by attention to hygiene, improving the general health, and by the administration of nerve tonics, quinine, strychnine, arsenic, nitrate of silver, and the like. Strychnine is certainly most useful when given hypodermically, one injection being given daily, in any convenient place. The nitrate of strychnine is the salt for the purpose; $\frac{1}{50}$ gr. may be gradually increased to $\frac{1}{20}$ gr. It is less effective than in progressive muscular atrophy, probably because the latter often occurs earlier in life.

Electricity may be tried, although it is generally unsuccessful. Erb has recommended the application of the voltaic current through the throat, the positive electrode being placed on the back of the neck, the negative stroked down the side of the pharynx externally, and such a strength being employed as shall produce reflex movements of deglutition; but it is difficult to discern any influence. Change of air is desirable in the early

stage, and rest is imperative. The patient should be discouraged from ineffectual attempts to talk. Food must be carefully regulated, easily digestible varieties being reduced to a semi-solid condition. In the later stages, should swallowing be impossible, nourishment must be administered by an oesophageal tube, or, what is better, by a catheter introduced through the mouth or nose, through which liquid food is given by means of a funnel.

(B) **Sudden Labio-Glosso-Laryngeal Paralysis.**—**SYNON.** : Acute or Apoplectiform Bulbar Paralysis.

DEFINITION.—Paralysis of similar distribution to that of the chronic form, with or without conspicuous wasting, of sudden onset. It is always due to a vascular lesion, usually thrombosis.

ÆTIOLOGY.—The causes of this affection are for the most part those which lead to sudden lesions elsewhere in the brain, especially degenerations of vessels, atheroma, and syphilitic disease. Very rarely injuries have been the apparent cause. It is a disease chiefly of late life.

ANATOMICAL CHARACTERS.—Little is known of the morbid changes in cases of sudden onset which have recovered with persistent symptoms. In cases which have died rapidly, foci of softening in the medulla have been found; and there is reason to believe that such softening, from vascular occlusion, is the general cause of the affection. Usually there is disease of one or both vertebral arteries, and closure of one or more branches which come off from the diseased part. Sometimes the diseased vertebral is much larger than the other, and its branches have taken the larger share in the blood-supply to the nuclei. Probably a small hæmorrhage may also give rise to it, but an extravasation here is seldom survived. The frequent symmetry of the symptoms in the sudden form, and their limitation to the parts which are affected in the chronic disease, show the close relation of the central structures, owing to which they are all affected by the one lesion: this is probably closure of one of the central branches. The wasting in some of the cases of this variety is very much less than that which follows an acute lesion of motor grey matter elsewhere. It is possible that the ascending fibres from the nuclei concerned pass up close to the middle line, in a situation in which all may be damaged by a single lesion.

SYMPTOMS.—The onset is sudden, often preceded by headache and giddiness, rarely attended by loss of consciousness. The patient suddenly finds a difficulty in swallowing and in articulation, with inability to protrude the tongue. The symptoms commonly attain their maximum in the course of a few hours or days. Respiratory disturbances may be present—cough, dyspnœa, and hiccup. Convulsions and weakness in the limbs, sometimes with tingling, occasionally occur at the onset of severe cases. Many, which present these symptoms, die in the course of a few hours. In those which recover, paralysis of the tongue, lips, throat, and larynx may remain, resembling that which characterises the chronic form, and there may or may not be conspicuous wasting. In many cases, however, the symptoms are incomplete, some part escapes, or the bilateral symmetry is imperfect. This we should expect from the more random character of the lesion. The disease differs from the chronic form also in 'not being progressive.

Unless a fresh sudden attack occurs, the patient may remain in the same condition for a considerable time, and may even improve. It is rare, however, for improvement to be considerable. A stationary condition of considerable palsy sometimes continues for months, rarely for a year or more. It is more common for other slight attacks to occur as other branches of the diseased artery become occluded.

DIAGNOSIS.—The diagnosis of the acute form of labio-glosso-laryngeal paralysis calls for little remark. It must be remembered that the symptoms may deviate from the type more than in the chronic variety, as the lesion sometimes produces irregular effects. It is chiefly liable to be confounded with the impairment of movements of the palate and tongue sometimes left after double hemiplegia, from which the history suffices to distinguish it, the two attacks of hemiplegia usually occurring at different times, and the hemiplegic symptoms being pronounced. The rare symmetrical affection of the cortical centres for the tongue, mentioned above, is also not simultaneous on the two sides, and it is associated with at least transient hemiplegic weakness much more obtrusive than that which accompanies the bulbar affection.

PROGNOSIS.—If the patient recovers from the immediate effects of the lesion, the prognosis of the paralysis of the lips, tongue, and other parts is better than in the chronic form, inasmuch as recovery of slightly damaged structures may lead to some restoration of power. The prognosis is also better if there is any reason to ascribe the mischief to syphilitic disease. Nevertheless, in some acute cases the paralysis remains in its initial degree, although even in these there is not the tendency to increase which is seen in the chronic variety.

TREATMENT.—Any causal indication must be carefully sought for in acute labio-glosso-laryngeal paralysis, and treated, especially evidence of syphilis. In other conditions the treatment is that for the vascular disease which is its cause, and which has been already described. Electrical treatment has little influence, nor can we anticipate the possible good from the hypodermic injection of strychnine which is occasionally obtained in the chronic form. The remarks regarding diet and feeding in the chronic form are equally applicable to the acute variety.

(C) **Acute Myelitic Bulbar Paralysis.**—**SYNON.** : Myelitis Bulbi.

In rare cases, symptoms of bulbar paralysis, as above described, come on in the acute (not sudden) manner characteristic of central inflammations, and depend on this process in the grey nuclei which are the seat of degeneration in the chronic form. Such cases, when the lesion is limited to this region, are too rare to make it necessary to do more than mention their occurrence. The process is analogous to spinal polio-myelitis, and the principles of its treatment are the same. It is more common for such an onset of bulbar symptoms to follow those of an ascending inflammation of the cord. They may also occur as the final stage in the mysterious disease, 'acute ascending paralysis,' in which it is probable that a toxic agent in the blood acts on certain parts of the nerve-centres and abolishes their function.

(D) **Pseudo-Bulbar Paralysis.**—The fact has been already mentioned that bilateral lesions of the cerebral hemispheres may cause symptoms

closely resembling those produced by disease of the nuclei of the medulla. This effect is due to the fact that the muscles paralysed, being bilateral in use, are represented in both hemispheres, and can be innervated from either; hence compensation by the other side prevents serious paralysis from a unilateral lesion; but if disease afterwards occurs in the part affecting the compensation, paralysis results such as is caused by disease of the medulla, or rather (since there is no wasting) by disease of the fibres from the cortex to the bulbar nuclei, homologous with those of the pyramidal tracts. The lesions causing pseudo-bulbar paralysis are usually in the cortical centres, rarely in the internal capsule, or in the outer parts of the lenticular nuclei, where they probably implicate the fibres in the white substance from the centres in the lower part of the motor region related to the lips, tongue, &c. The lesions may be of any kind, but are generally sudden and due to vascular disease causing symmetrical thrombosis. Hemiplegia usually attends the onset, and constitutes a distinguishing feature of these cases.

W. R. GOWERS.

LACRYMAL APPARATUS, Diseases of (*lacrima*, a tear).

The lacrymal apparatus consists of the gland, with its excretory ducts; and of the puncta, the canaliculi, the lacrymal sac, and the nasal duct, through which the secretion is conveyed into the nose. The diseases of this apparatus are almost limited, with the exception of growths affecting the gland itself (*see* ORBIT, Diseases of), to the excessive secretion of tears, and to impediments to their escape into the nose. To excessive secretion, or to impeded outflow, the common term *epiphora* has been applied; but the great majority of cases of epiphora are due to the latter of the two causes.

Epiphora.—*Excessive secretion of tears* is, in some cases, an affection for which it is not possible to discover an adequate cause, and it may perhaps be sometimes due to the prolonged operation of emotional influences. In most instances, however, it is associated with some kind or degree of conjunctival irritation, and is to be regarded only as a reflex phenomenon hence arising. It is well known that any temporary or accidental irritation, such as may arise from the intrusion of a foreign body into the conjunctival sac, is apt to be followed by a copious secretion of tears, which assist in dislodging the offender; and irritations of a more chronic kind, produced by congestion or irregularity of the lining membrane of the lids, may have a similar effect.

Impediments to the escape of the tears, causing them to collect in the conjunctival sac, or even to flow over the cheek, may depend upon displacement of the puncta, so that these apertures are no longer applied to the conjunctival surface, from which they normally remove superabundant moisture by capillary attraction. Such displacements affect chiefly the punctum of the lower lid; and may be consequent either upon conjunctival swelling, by which the lid is pushed away from the eye, or upon paralysis or weakness of the orbicularis muscle, which allows the lid to fall by the action of gravity. In some cases epiphora will depend upon obliteration or occlusion of the puncta. The former condition is incurable; the latter may be produced by plugs of inspissated mucus, which may be removed by the careful employment of a probe.

But the most ordinary cause of obstruction is stricture of the nasal duct, in which condition the tears are arrested a little below the sac, and the sac consequently becomes over-distended. In such cases the sac can be seen and felt as a small lump situated just beneath the *tendo oculi*. When pressure is made upon this lump, a fluid, consisting of tears mixed with more or less mucus or muco-pus, will regurgitate into the eye, and the lump itself will disappear. The danger in such cases is that the continued distension of the sac and the intrusion of bacteria will in time excite inflammation of the lining membrane, leading to the formation of pus, and this to an opening upon the cheek, producing what is called a *lacrymal fistula*. Such an opening never heals until the duct is again pervious, and it is liable to undergo periodic attacks of unsightly inflammation.

TREATMENT.—In all cases of lacrymal hypersecretion, the first thing to be done is to search under the lids for any concealed foreign body which may be lurking there. If none be detected, examination must be made for conditions likely to be irritating; and they are to be treated, if they exist, by mild astringent or other suitable local applications. There is probably no medicine which can be said to exert any positive effect in diminishing the amount of the lacrymal secretion.

If the displacement of the lid can be cured by treatment addressed to its causes, the tears will usually return to their accustomed channel. If the displacement be incurable, as happens in some cases of paralysis of the *portio dura*, or of chronic ectropion, the patient may often be relieved by slitting open the canaliculus as far as the caruncle, so as to carry back the aperture to the secretion which it is designed to remove.

The treatment of stricture of the nasal duct can often be only palliative. The patient should acquire the habit of emptying the distended sac by finger-pressure many times a day, and of wiping away the fluid; while, to diminish the irritation of the mucous membrane, a drop of any mild astringent lotion may be applied to the inner corner of the conjunctiva two or three times a day, immediately after such pressure has been made. Perhaps the lotion most generally suitable for this purpose is a solution of acetate of lead in distilled water, of a strength not exceeding three grains to the fluid ounce.

When a radical cure is desired, the canaliculus must be slit up, and the patency of the duct restored by the passage of probes through the stricture. If fistula has already formed, or even if the sac is the seat of an abscess, no other plan is available; but for the necessary details the reader is referred to works on ophthalmic surgery.

R. BRUDENELL CARTER.

LACTATION, Disorders of (*lacto*, I give suck).—**SYNON.**: *Fr. Troubles de la Lactation*; *Ger. Störungen der Milchdrüsen*.—The disorders of lactation are numerous. Sometimes the quantity of the lacteal secretion is excessively small and quite inadequate for the support of the child. At other times it is so abundant that the milk will flow from one nipple as the infant is sucking the other; and when the child is removed from the breast, the secretion continues from both sides. The term *agalactia* is applied to the former, and *galactorrhœa* to the latter condition.

1. **Agalactia** (ἀ, priv. ; γάλα, milk).—Agalactia signifies either a total suppression of the mammary secretion, or a very scanty supply. It results generally from anæmia and general debility.

The treatment should be directed towards improving the health of the patient as much as possible, by a generous and judicious diet, and tonics, particularly those containing iron. Recent physiological observations show that a proteid diet has a marked effect in increasing the secretion of milk. Certain drugs have been employed as galactagogues, and, it has been said, with benefit. The leaves of the castor-oil plant, boiled, have been used as a local application—the liquid for fomentation, and the leaves as a poultice ; and a strong decoction of the same plant has been given as a drink. It is doubtful, however, whether such remedies are efficacious. See GALACTAGOGUES.

2. **Galactorrhœa** (γάλα, milk ; ῥέω, I flow). This occurs in two forms. In the one the composition of the milk is normal, but the quantity excessive ; in the other form the increase in the bulk of the secretion is due to a preponderance of the watery part of the fluid.

The chief remedies employed to reduce the amount of the mammary secretion are belladonna and iodide of potassium. Belladonna is employed as an outward application, as well as administered internally. The extract rubbed up with glycerine may be spread on lint, and thus applied to the breasts, or the Emplastrum belladonnæ may be used. The child should not be put to the breast too frequently. If the excessive secretion continue for any length of time, great emaciation may result ; and to this condition the term *mammary diabetes* has been applied. Under such circumstances lactation should be entirely stopped as soon as possible. Strapping the breasts tightly immediately after they have been emptied is of use. Every care must be taken to avoid the formation of a mammary abscess ; and if the breasts get hard and knotty a breast-pump should be employed to free the tubes.

3. **Depressed Nipples**.—Depressed nipples are generally produced by the pressure of stays. If this condition be observed during pregnancy, periodic attempts should be made to draw the nipples out by means of a glass nipple-shield, to which an india-rubber tube and teat is attached.

4. **Fissures and Excoriations of the Nipples**.—These often lead to abscess, and it is said that they may sometimes end in malignant disease. To avoid the occurrence of these lesions, astringents should be applied to the nipples during pregnancy, in order to harden them. Eau-de-Cologne and water, brandy and water, or a weak solution of tannin, may be employed for this purpose. Or the nipple may be anointed with pure vaseline, lanoline, or cacao-butter, and gently manipulated between the finger and thumb. This is highly recommended by some.

Sometimes an abrasion on the surface forms an ulcer or a crack at some part of the nipple, most frequently at its base, which gives rise to great pain during suckling. The remedies for these cracks are astringent applications, such as tannin, flexible collodion, a weak solution of nitrate of silver or of carbolic acid. Care should be taken to sponge these away before the infant is again put to the breast ; and a nipple-shield with an india-rubber teat will be found of great service.

For abscess and other morbid conditions of the

mammary gland supervening during lactation, see BREAST, Diseases of ; and NIPPLE, Diseases of. CLEMENT GODSON.

LAGOPHTHALMOS (λαγώς, a hare ; and ὀφθαλμός, the eye).—This term is derived from an old supposition that the hare sleeps with its eyes open ; and is applied to a condition in which there is inability to close one or both eyes. Lagophthalmos may be due to paralysis of the orbicularis muscle, in which case it will be attended by falling of the lower lid, and will generally be associated with paralysis of other muscles supplied by the seventh nerve (see FACIAL PARALYSIS) ; to the contraction of cicatrices ; to spasm of the upper eyelid (see THIRD NERVE, Diseases of) ; or possibly to congenital malformation of the lids. In paralytic lagophthalmos, the treatment is that of facial paralysis. Where there is contraction or deformity, each case must be considered on its own merits, with regard to the possibility of obtaining relief from a surgical operation. R. BRUDENELL CARTER.

LALLING.—The term used to characterise the speech of children before they have learned to pronounce their words quite intelligibly and such defects of speech as may resemble this (Kussmaul).

LANDRY'S PARALYSIS.—See SPINAL CORD, Diseases of—Acute Ascending Paralysis.

LANGEN - SCHWALBACH, in Nassau.—Chalybeate waters. See MINERAL WATERS.

LARDACEOUS DISEASE (*lardum*, bacon).—A synonym for amyloid disease, which is so called from the supposed resemblance of the cut surface of an affected organ to raw bacon. See AMYLOID DISEASE.

LARYNGEAL PHTHISIS.—A term applied to laryngeal tuberculosis. See LARYNX, Diseases of ; and PHTHISIS.

LARYNGISMUS STRIDULUS (*larynx*, the windpipe ; *stridor*, a noise).—A form of obstructed breathing, attended by a peculiar stridor or crowing sound during inspiration, and dependent on spasm of the muscles of the glottis. See LARYNX, Diseases of.

LARYNX, Clinical Examination of the.—Successful examination of the larynx depends, like all other objective investigations, upon practice and suitable appliances. The first essential is a suitable light, placed upon one side of and behind the patient's head, so that it can be reflected into the throat from a concave mirror of 15" focal length adjusted over the eye of the observer, on the same side as the light, and in such manner that, while he gets clear vision through the hole in the centre, his eye is protected from the glare of the lamp. A bull's-eye lantern with a black chimney is generally used in this country, though on the Continent an ordinary Argand gas-burner with clear glass chimney is preferred. But as the quantity of light required is in direct proportion to the illumination of the room, it follows that the darker the latter the more easily will the interior of the larynx be revealed. A candle in a dark room will often be more successful than the lime-light in a chamber brilliantly lighted. The design of the reflecting mirror is not of much consequence, though most specialists prefer one or

other form of the spectacle frame, if fitting truly, as it is more quickly placed in position, while its pressure is less irksome than the kind adjusted with a head-band. In any case the central orifice must be so placed directly in front of the eye that, without any turning of the head to one side, perfect vision is obtained. By closing each eye in succession, with the reflector in position, it may be at once ascertained whether both eyes are directed upon the region under examination, thus securing the advantage of double vision.

The laryngoscope itself consists in the small pharyngeal mirror, in which the view of the larynx is obtained while the light is thrown downwards by the same means. The mirror should be adjusted to the stem at an angle of about 120° ; but the stem should be sufficiently flexible to enable the angle to be altered at pleasure. Three or four sizes should be in use, the smaller generally being preferable, partly because they can be placed further upwards and backwards under the uvula, and partly because, in that they do not irritate so large a surface, they produce less tendency to reflex action. The latter is the real difficulty in making an examination, and only practice will enable the observer so to place his instrument as to produce the minimum amount of irritation. No rules will help the beginner very much. Suffice it to say that, after drawing the patient's tongue out by holding it between the finger and thumb of the left hand, and thereby keeping the head fixed in one position, slightly tilted backwards, the laryngoscope must be placed as far back as possible, doing so gently and firmly and without touching the back of the tongue, the aim being to lift upwards the tip of the uvula with the further edge of the mirror, so that the latter may be thrust as far back as possible. The mirror must be held as nearly horizontally as is consistent with obtaining the reflection from its surface, this being often facilitated by tilting the patient's head further upwards. In consequence of the importance of being able to alter the inclination of the head, it is obviously a mistake to allow the patient to hold the tongue out himself; indeed this should be done only when the observer's second hand is needed for making an application to the larynx, or for inserting an instrument. Occasionally even with the utmost skill and patience it is impossible to obtain a view in the manner described, chiefly in consequence of the elevation of the back of the tongue. In this case it will sometimes prove of great help to depress the tongue with a tongue depressor instead of pulling it out: thus a view may be obtained of the laryngeal structures when the patient utters the sound 'A' or 'Ah,' though the view thus obtained is seldom more than momentary. In other cases the difficulty arises from an exaggerated degree of irritability of the pharynx, so that, the moment tongue or pharynx is touched, contraction of the constrictors takes place, rendering a view of the structures below impossible. Practice will often overcome this difficulty, especially if the patient presents himself with an empty stomach. Brushing the pharynx with a 5 or 10 per cent. solution of cocaine is often recommended, although the extreme discomfort thereby induced often intensifies the patient's nervousness, while at the same time it lessens the local sensitiveness. Consequently a local anæsthetic should be used only as a last resource. The most difficult part of the larynx to discover is the anterior commissure and

anterior wall of the trachea. Assistance is gained by instructing the patient to phonate the sound *E* rather than *A*, though, with tongue held out of the mouth, a consummation of the attempt is not possible. At any rate the epiglottis is thereby raised and brought forwards and the glottis more completely exposed. Further help is sometimes gained by increasing the backward inclination of the head and then making the plane of the laryngeal mirror more horizontal with the plane of the glottis. Often by making a patient laugh or cry the inspection of the anterior commissure is facilitated.

During an examination every structure capable of being thus revealed must be passed in review, and frequently, especially with an expert, every point of importance can be grasped in a momentary examination. The beginner, however, must expect to find several inspections necessary before he has mastered all the points of importance; at the same time he must remember that the more often he makes his examination at the same sitting the more irritable the patient's throat will become. The vocal cords will always be the landmarks from which we estimate our success in obtaining a proper view, their normal pearly white, or, in adult males, pink colour, making them very conspicuous; but where they are so greatly swollen and injected as to make their nature difficult of recognition, it is sometimes troublesome to find contiguous structures accurately. Again, the supra-glottic regions may be so much swollen as to conceal the true cords, a condition which adds to our difficulties. Besides the true cords, the false cords or ventricular bands, the aryænoïd cartilages, the aryæno-epiglottic folds, and the epiglottis must be passed in review. Nor must it be forgotten that the base of the tongue and lower portions of the pharynx are as fully revealed by the laryngoscope as the larynx proper, and that their omission from examination often betrays the inexperience of the laryngoscopist.

GREVILLE MACDONALD.

LARYNX, Diseases of.—The principal diseases and disorders which affect the larynx may be conveniently enumerated and described in the following order:

1. Disorders of Circulation, p. 845.
2. Inflammation, p. 846.
3. Leprosy, p. 848.
4. Lupus, p. 848.
5. Nervous Affections, p. 848.
6. Spasm, p. 850.
7. Syphilis, p. 850.
8. Tuberculosis, p. 851.
9. Tumours, p. 853. See also CROUP; DIPHTHERIA; PAIN IN VISCERAL DISEASE; and TRACHEA, Diseases of.

1. Larynx, Disorders of Circulation of.—*Anæmia* of the larynx does not exist as a separate disease. Like pallor of the gums, it is described as one of the symptoms of incipient phthisis.

Congestion of the larynx requires a passing notice. Hyperæmia of some portion of the mucous lining of the larynx results from over-exertion of the voice, exposure to cold, the action of irritants, or any cause obstructing the circulation through the larynx; and it may be consecutive to laryngitis. It causes more or less persistent hoarseness, and a sense of discomfort in the throat; and it excites what is commonly called a 'tickling cough.' Congestion is clinically inseparable from laryngitis.

TREATMENT.—Treatment of congestion of the larynx is unnecessary, beyond resting the voice, if the congestion is merely temporary. If more persistent, astringents should be applied locally, as in cases of chronic laryngitis.

2. **Larynx, Inflammation of.**—The varieties of laryngitis treated of here will be considered under the following headings: (a) **Acute**—including i. *Catarrhal*; ii. *Phlegmonous*. (b) **Chronic**.

(a) i. **Acute Catarrhal Laryngitis.**—SYNON.: *Laryngitis Catarrhalis*; *Cynanche Laryngea*; Fr. *Laryngite Aiguë Catarrhale*; Ger. *Kehlkopfentzündung*.

DEFINITION.—Acute catarrhal inflammation of the mucous membrane of the larynx.

ETIOLOGY.—Laryngitis is more common among males than females, and among children than adults. The most frequent exciting cause is exposure to cold, but the disease may often be attributed to sudden changes of temperature, a damp or irritating atmosphere, the inhalation of acid vapours or gases, excessive use of the voice, and to the abuse of alcohol, hot drinks, and spices. It may be due to accidental attempts at swallowing boiling water. The catarrhal process may be propagated from the pharynx or nose. It occurs also as a complication of exanthematous fevers—especially of measles. Sedentary occupations, and anything that depresses the vitality of the body, may predispose to laryngitis.

ANATOMICAL CHARACTERS.—Acute laryngitis is characterised by the changes common to catarrhal inflammation of other mucous membranes—hyperæmia, swelling, and increased secretion. Small superficial erosions may occasionally occur, especially at the posterior extremities of the vocal cords, but ulceration does not extend below the epithelial layer.

SYMPTOMS.—A mild attack of laryngitis commences with hoarseness, irritable cough, and a sense of tickling and soreness about the larynx, without any febrile disturbance. Subsequently the voice may be completely lost. In severe cases the patient becomes restless and anxious; experiences a feeling of constriction about the rima; complains of sore-throat in swallowing; and points to the larynx as the seat of pain. The breathing is altered, having more or less the characteristics of laryngeal obstruction, namely, the long-drawn hissing inspiration, prolonged expiration of the same character, but with less of the sibilant sound, and diminution or complete abolition of any pause between successive respiratory efforts. The voice also is altered, becoming husky and uncertain, deeper in tone, and croaking in quality. The patient likewise suffers from cough, of the same character as the voice; from the imperfect closure of the vocal cords it wants sharpness, is husky, and sometimes is accompanied by a hollow, clanging sound, constituting what is commonly called the *croupy cough*. The expectoration varies according as the inflammation involves the larynx alone, or extends to the trachea and bronchi. In the former case it is usually clear, thin, tenacious mucus, which is *hawked* rather than coughed up, mixed with the saliva, which is freely secreted but not swallowed. Sometimes the expectoration contains harder pellets, secreted in the ventricles of the larynx; while, if the trachea and bronchi are involved, the usual thick expectoration of bronchitis is also coughed up. Deglutition is painful and difficult, owing to implica-

tion of the aryteno-epiglottic folds and epiglottis; yet the pharynx, on inspection, shows only a little redness, quite inadequate to account for the dysphagia. Accompanying these symptoms there is a rapid pulse, and slight rise of temperature, though the tongue may be moist, and other indications of inflammatory fever slight.

The laryngoscope reveals congestion of the larynx, which varies much in extent and degree. In slight cases the reddening may be confined to special parts, like the epiglottis and vocal cords, without any appreciable swelling of the affected structures. The cords usually exhibit changes, which account sufficiently for the hoarseness. During attempts at phonation they are often seen to be imperfectly approximated, being separated by an elliptical fissure, the result of paresis of their internal tensor muscles, the thyro-arytenoidei interni. Less frequently the posterior part of the glottis remains open during phonation, forming a triangular space with the apex directed forwards, a condition depending on paresis of the arytenoideus muscle. These pareses of the cords are probably due to inflammatory implication of their neuro-muscular apparatus. Protrusion of the swollen inter-arytenoid fold between the posterior ends of the cords, preventing their due adduction, is an occasional source of hoarseness. At other times no definite loss of movement can be recognised, and here the hoarseness is to be ascribed to alterations in the tension and vibration of the cords produced by the catarrh. In the severe type the whole larynx is congested, and the aryteno-epiglottic folds, epiglottis, and ventricular bands are swollen so as to hide the vocal cords more or less.

In most instances of the mild form, recovery ensues in a few days.

If the case progress untowardly, the restlessness and anxiety increase; suffocative paroxysms occur and recur with increasing frequency; the patient's whole attention appears concentrated on the effort of breathing; he dreads to speak or swallow, and if obliged to say anything, he takes first a laboured inspiration, and then, with a straining effort, brings out what little voice is left. Gradually, as the aëration of the blood becomes more imperfect, drowsiness comes on; the eyes, staring in the previous stage, are half closed by the drooping lids; the face, bathed in perspiration, becomes livid; and death occurs, probably in a paroxysm of suffocative dyspnoea.

Acute laryngitis occurring in young children, sometimes termed *spasmodic laryngitis* or *false croup*, differs somewhat from the description just given. These differences depend on the small size of the child's larynx, and on the tendency to spasm incidental to this age. Without any previous illness beyond, possibly, a slight cough and hoarseness, the child is suddenly seized at night with a barking cough, noisy stridulous inspiration, and more or less urgent dyspnoea. The suffocative seizure seldom lasts more than a few minutes; but it may recur the same night, or on successive nights, the child being generally free from all symptoms, except slight cough and hoarseness, during the daytime. These attacks are mainly due to spasm of the sphincter muscles of the larynx; but in all probability they are also partly the result of drying of the secretions accumulated during sleep, and consequent narrowing of the glottis. Paroxysmal dyspnoea of the same nature, and due to the same cause, may develop as a complication of the exanthemata, especially measles.

DIAGNOSIS.—Acute laryngitis is apt to be confounded with that form of inflammation which is characterised by the formation of a false membrane in the larynx, namely, croup or laryngeal diphtheria. If practicable, a laryngoscopic examination, showing the absence of false membrane, is the most certain means of diagnosing simple from membranous laryngitis; but even where perfect casts of the trachea, bronchi, and primary bronchia are expectorated, the larynx may be absolutely free from false membrane, and simply inflamed. The absence of diphtheritic membrane in the fauces, of acrid excoriating discharge from the nostrils, and of glandular swellings, as well as the mode of accession of the symptoms, would lead us to regard the case as simple laryngitis; while the presence of any of these symptoms, or the prevalence of an epidemic of diphtheria, would lead us to suspect false membrane. Even after due consideration of these points, and of the character of the voice, cough, &c., in certain cases, we are unable to say whether we have to deal with simple or with membranous laryngitis. The acute laryngitis or false croup of children is further distinguished from membranous croup by the sudden accession of the symptoms at night, and by the progress of the case—true croup or diphtheria increasing in intensity, while, from the first sudden onset of the symptoms, false croup diminishes, unless complicated with lobular pneumonia or other severe disease. In many cases bacteriological examination of the secretions from the larynx or fauces will alone enable us to exclude diphtheria. From laryngismus stridulus, acute laryngitis is distinguished by the presence of slight pyrexia and other indications of primary inflammatory affection of the larynx and air-passages; by the absence of indications of any other affection of the nervous system, or of a tendency to convulsions; by the usual occurrence of the attack in the night only; by the slighter affection of the breathing; and by the frequent *croupy cough*, which is the prominent symptom, and which is wanting in laryngismus.

PROGNOSIS.—In mild attacks of laryngitis all the symptoms exist only in a slight degree, and disappear in a few days under simple treatment. Such is the ordinary course of the false croup of children. In adults laryngitis may occur in any degree between the mildest form and that in which, the symptoms being all most intense, it may prove fatal in a day or two, or even in a few hours. The danger depends in great measure on the amount of swelling present. Although mild laryngitis usually terminates favourably in a few days, it is necessary that every case should be sedulously watched, as at any period dangerous symptoms may set in and prove rapidly fatal. The disease is most deadly in the young. Acute may pass on to chronic laryngitis.

TREATMENT.—As soon as the first indications of even slight laryngitis are observed, the patient should be confined to a warm room, at a temperature of 65° F., a kettle being kept boiling to moisten the atmosphere. Talking must be forbidden, in order to ensure as much rest to the larynx as possible. The diet should be chiefly liquid, and no stimulants are required. As a rule, no further treatment is necessary; but, if the cough be troublesome, we may prescribe a saline diaphoretic draught, with small doses of morphine, and 4 or 5 minims of antimonial wine every three or four hours. The cough and sense of dryness, or soreness of the throat, are generally relieved by the

inhalation of simple steam, or by the vapour of compound tincture of benzoin, one drachm being added to a pint of hot water. In every case a regular evacuation of the bowels is to be secured. If swelling of the larynx ensue, the patient must be directed to suck ice constantly. Should the dyspnoea become urgent, tracheotomy must be performed at once. With due care in the performance of the operation and after-treatment of the patient, in cases of simple laryngitis, tracheotomy is almost always successful, but it should not be resorted to unless the case is urgent.

Simple cases of false croup in children are usually relieved by warm poultices to the throat. An emetic may be administered in the comparatively rare instances in which dyspnoea depends on insufficient removal of secretions from the larynx.

ii. **Phlegmonous Laryngitis.**—**SYNON.** : *Œdema Glottidis*; Œdema of the Larynx; Œdematous Laryngitis; Fr. *Laryngite Œdémateuse*; Ger. *Kehlkopfödem*.

DEFINITION.—Inflammatory exudation into the submucous tissue of the larynx of serous, sero-purulent, or sero-fibrinous fluid.

ÆTIOLOGY.—Phlegmonous laryngitis occasionally arises as a primary disease, and is then to be regarded as a symptom of septic infection; thus in rare instances it seems to have been the earliest manifestation of erysipelas.

Mechanical injuries, and the direct action of boiling water, corrosive poisons, and foreign bodies are less uncommon causes. Phlegmonous laryngitis may also develop in the course of specific fevers, such as measles, scarlatina, small-pox, typhoid fever, diphtheria, pyæmia, and in renal disease.

In most cases, however, the laryngeal affection is the result of extension of disease from neighbouring parts, pharyngitis, whether dependent on erysipelas or other causes, being the most common antecedent.

Inflammatory affections of the cervical connective tissue, and perichondritis, or deep ulceration of the larynx, associated with carcinoma, syphilis, or tuberculosis, are also occasional causes of phlegmonous laryngitis.

ANATOMICAL CHARACTERS.—The mucous surface presents a dull red or livid colour, and is greatly swollen, owing to infiltration of the submucosa. A certain amount of pus is generally diffused through the exudation, but it is rare for a circumscribed abscess to form. The process usually attacks first the aryæno-epiglottic folds and the epiglottis, and it may extend thence to the ventricles and other parts of the larynx, the vocal cords themselves being seldom affected. The submucous tissue below the vocal cords, lining the cricoid cartilage, may very occasionally be the sole seat of the disease.

SYMPTOMS.—The symptoms indicative of severe laryngitis exist in an increased degree in this affection, the swelling of the epiglottis interfering especially with deglutition, and that of the aryæno-epiglottic and ventricular bands causing very dangerous dyspnoea. By examination with the finger and, far better, by the laryngoscope, we observe further the physical condition caused by the swelling. The epiglottis is congested, misshapen, rounded like a chestnut, or having its two sides swollen so as to resemble two mucous bladders pressed together in the middle line; and, unless this hides the rest of the larynx, the aryæno-epiglottic folds will be recognised as two long rounded

swellings, passing from before back, and nearly meeting in the centre, the ventricular bands being visible only when there is little swelling above. The prognosis in such cases is extremely grave.

TREATMENT.—The patient should suck small pieces of ice, leeches might be applied over the larynx, and an attempt may be made to reduce the swelling by scarification with a curved laryngeal bistoury, but in most instances tracheotomy is required.

(b) **Chronic Laryngitis.** — **DEFINITION.** Chronic inflammation of the mucous membrane of the larynx.

ÆTIOLOGY.—Chronic laryngitis is often, but not invariably, a sequel of acute laryngitis, and is due to the same causes. Chronic affections of the nose and pharynx frequently co-exist, and seem in some instances to be the starting-point of the malady.

ANATOMICAL CHARACTERS.—The mucous membrane of the larynx is hyperæmic, and may be slightly swollen, the vessels being often dilated in patches. The morbid process may extend in rare cases to the submucosa, producing diffuse connective-tissue thickening, or small warty growths, especially on the vocal cords—‘*chorditis tuberosa*’ of Türk. Marked enlargement of the veins on the epiglottis is occasionally observed, and is probably the result of the chronic catarrh.

SYMPTOMS.—The symptoms of chronic laryngitis are hoarseness or aphonia after slight exertion of the voice; a hacking cough, with but little of the brassy, laryngeal character; either no expectoration, or only a little tenacious mucus; and a sense of dryness and tickling, with slight pain, in the throat.

The laryngoscope shows a varying amount of congestion, either general or local, but the hyperæmia is seldom so pronounced as in acute laryngitis. The cords are usually affected, presenting a pinkish, slightly thickened appearance.

Mucous secretion is often seen sticking to the inter-arytenoid fold or to the anterior angle of the glottis. In a special variety of the disease, known as ‘*laryngitis sicca*,’ the secretion is apt to dry and form adherent scales or crusts, in consequence of some modification of its composition. Epithelial erosions are not uncommon, but ulceration never occurs. Pareses of the vocal cords often ensue, giving rise to changes in the glottis, as described under Acute Laryngitis.

In the rare instances in which thickening invades the subglottic region, stenosis commonly ensues, and obstructive dyspnoea becomes a prominent symptom.

DIAGNOSIS.—In cases of chronic disease of the larynx a laryngoscopic examination is indispensable. Without the laryngoscopic diagnosis and treatment can be only guess-work; with it, the appearances described above are clearly recognised. Where chronic laryngitis is persistent, the possibility of tuberculosis must be kept in mind, and repeated examination of the lungs and sputum should be made. In elderly or middle-aged patients a localised swelling and congestion of one of the vocal cords, especially if associated with impaired mobility, should arouse the suspicion of carcinoma.

PROGNOSIS.—Chronic catarrhal laryngitis may subside spontaneously, but is usually persistent unless properly treated.

TREATMENT.—Any imprudence in diet or hygiene must be corrected, pungent condiments or

spices, very hot drinks, alcohol in excess, smoky or dusty rooms, being avoided, and the voice rested as much as possible. About every other day the larynx should be brushed out with an astringent lotion. In mild cases a solution of chloride of zinc, 30 grains to the ounce, will suffice; but if this fail, a more powerful astringent, nitrate of silver 10 to 40 grains to the ounce, should be employed. Such applications should not be continued for more than two or three weeks at a time.

Inhalations of chloride of ammonium, pine-oil, and creosote are recommended by some physicians. In some obstinate cases the waters of Ems, Reichenhall, Marienbad, Aix-les-Bains, and other spas are believed to yield good results. Attention must be paid to the general health, and to the state of the digestive organs.

3. **Larynx, Leprosy of.**—**ÆTIOLOGY.**—The causes are identical with those of leprosy in other situations. Leprosy of the larynx may be associated with a similar affection of the buccal mucous membrane, the tongue, and the palate.

ANATOMICAL CHARACTERS.—The lesions at first consist of a nodular thickening of the epiglottis and aryæno-epiglottic folds, which may be succeeded by very chronic ulceration and cicatrization. Ultimately the disease may invade other parts, and cause stenosis of the larynx.

SYMPTOMS, COMPLICATIONS, AND DIAGNOSIS. The symptoms of laryngeal leprosy are those of chronic inflammation; and, if the nodules ulcerate, the ulceration is very slow, and not of the destructive character of syphilis. As leprosy of the larynx occurs only when the disease of the skin has been long established, its diagnosis is clear. It usually exists for a long time, even years, before it ulcerates; and even after this it is very slow in its progress, and not fatal.

TREATMENT.—As in other forms of leprosy, treatment is almost useless. Tracheotomy must be performed if stenosis occur. *See* LEPROSY.

4. **Larynx, Lupus of.** — **ÆTIOLOGY.** — Although in all probability a form of tuberculosis, this condition has characteristic clinical features. The larynx may be primarily affected.

ANATOMICAL CHARACTERS.—Small nodules appear on the epiglottis, and subsequently on the aryæno-epiglottic folds and other parts of the larynx, associated sooner or later with thickening and occasionally with ulceration and scarring of the mucous membrane.

SYMPTOMS, COMPLICATIONS, AND DIAGNOSIS. Lupus of the larynx may give no definite symptoms, even when pronounced lesions exist, and doubtless on this account this affection of the larynx is often overlooked. In other cases the symptoms are those of chronic inflammation. Lupus is distinguished from syphilis and ordinary tuberculosis by its prevailing nodular character, and by the rarity of ulceration. It lasts for many years.

TREATMENT.—Lupus of the larynx must be treated constitutionally in the same way as other forms of tuberculosis, and locally by caustics or the galvanic cautery. Lactic acid, applied as in other cases of laryngeal tuberculosis, is of service.

5. **Larynx, Nervous Affections of.**—(1) **SENSORY DISORDERS OF THE LARYNX.**—*Hyperæsthesia* of the laryngeal mucous membrane is a usual accompaniment of inflammation, acute and chronic, and is a not infrequent symptom of hysteria, hypochondriasis, and neurasthenia. *Anæsthesia* occurs

in cases where the superior laryngeal nerve or its centre is affected, and especially as a sequel of diphtheria. It is also an occasional symptom of bulbar paralysis and hysteria, and is said to accompany epileptic fits. *Hemianæsthesia* may result from tumours of the base of the skull. *Paresthesia*, in which the larynx is the seat of various perverted and unaccountable sensations, is not an uncommon manifestation in anæmic, hysterical, and hypochondriacal patients.

(2) MOTOR DISORDERS OF THE LARYNX.—
(a) *Spasm* is considered in a separate section. See 6. Larynx, Spasm of.

(b) *Paralysis* of the larynx is of great variety. It will be best discussed, first, under the head of the *nerves* affected; and, secondly, with respect to the individual *muscles* paralysed.

i. *Paralysis of the Nerves*.—*Paralysis of the Superior Laryngeal Nerve*.—In this rare condition, depending either on diphtheria or bulbar paralysis, the interior of the larynx is quite insensitive to the introduction of a probe; the epiglottis lies motionless against the base of the tongue, owing to paralysis of its depressors—the thyro-epiglottic and aryteno-epiglottic muscles; and the voice is said to be rough and low-pitched, from palsy of the crico-thyroid muscles. The glottis is represented by a wavy line, in consequence of paralysis of the external tensors. The immobility of the epiglottis and the anæsthesia are a source of great danger, as food is likely to enter the larynx and lead to pulmonary complications. Food must be administered by the œsophageal tube in such cases. See LABIO-GLOSSO-LARYNGEAL PARALYSIS.

Paralysis of the Recurrent Laryngeal Nerve.—Complete paralysis is generally due to pressure of an aneurysm of the aorta or other intrathoracic tumour, or of a goitre, on the nerve after its origin from the vagus, but the same effect may follow degenerative or destructive lesions of the motor fibres in any part of their course from the medulla oblongata down to their peripheral termination. Bilateral paralysis, in the very rare instances in which it has been observed, was the result of carcinoma of the œsophagus, double aneurysm of the aorta and innominate artery, tumours of the base of the brain, extensive pericardial effusion, and, lastly, pressure on the trunk of one pneumogastric nerve, for example, by enlarged bronchial glands. The symptoms of bilateral paralysis are aphonia, inability to cough, and slight stridor. Slight dyspnoea may be induced by attempts to speak. The vocal cords are seen lying motionless and relaxed, in a position midway between abduction and adduction. In unilateral paralysis, which is the usual form and is more common on the left side, one cord alone occupies the position just described, but, as the healthy cord crosses over the middle line during phonation to meet its palsied fellow, there is no aphonia, though the voice is generally weak and uncertain.

Hitherto complete paralysis alone has been considered; but paralysis depending on structural disease of the fibres or nuclei of the recurrent laryngeal nerves is far more often incomplete. In these circumstances the fibres supplying the abductor muscles are the first to suffer. In course of time the adductors may become affected also, but paralysis of these muscles is seldom complete. This fact is attributed to a greater vulnerability of the abductor nerve-fibres than of those supplying

their antagonists, the adductors. Semon believes that the abductor muscles themselves are less resistant than the adductors.

ii. *Paralysis of Individual Muscles*.—*Bilateral Abductor Paralysis*.—The cause may be either central—as in tabes dorsalis, bulbar paralysis, syphilitic or other intracranial disease; or peripheral—lesions of both recurrent or pneumogastric nerves, pressure on the trunk of one vagus, or degenerative affections of the abductor muscles, as described under the preceding heading. The symptoms are severe inspiratory dyspnoea and stridor, and weakness or slight hoarseness of the voice. With the laryngoscope the cords are found lying close together, being separated by a mere chink. On phonation they approximate as usual, but during deep inspiration no divergence takes place, and a slight movement of adduction is generally observed. This action is attributed either to the effects of suction, or to a perverted innervation of the unopposed adductors. Bilateral paralysis may cause fatal suffocative attacks, and, if persistent, necessitates the performance of tracheotomy.

Abductor paralysis may be simulated by mechanical fixation from ankylosis or arthritis of the crico-arytenoid joints, or by cicatricial or inflammatory changes in their neighbourhood. Diagnosis is often difficult in such cases, but in the latter condition there is usually some distortion of parts, such as contraction, irregularity, or swelling about the arytenoid cartilages, which is not the case in paralysis.

Unilateral Abductor Paralysis.—This condition is generally attributable to peripheral causes, and especially to compression of the left recurrent laryngeal or vagus nerve within the thorax by an aneurysm or other tumour. Palsy of the right abductor is an occasional result of chronic disease of the apex of the right lung.

The affected vocal cord occupies the median position; but if the adductor becomes involved, the cord recedes from the middle line and takes up a situation between that of abduction and adduction. The symptoms of unilateral paralysis are slight hoarseness and dysphonia, but dyspnoea and stridor do not occur except on exertion.

Paralysis of the Adductors.—Paralysis of these muscles is nearly always bilateral, and is probably the result of a central nervous affection of a functional nature, occurring in hysterical, neurotic, or anæmic subjects. It is doubtful whether gross nervous disease ever leads to isolated paralysis of the adductors. The patient, generally a female, becomes suddenly aphonic, but the reflex acts of sneezing and cough are still attended by the usual sound. Attempts to speak occasion a slight degree of dyspnoea, due to the escape of breath through the widely open glottis. The laryngoscope shows that the cords are abducted normally, but do not approach one another during efforts to phonate.

Paralysis of the Internal Tensors.—The internal tensors or thyro-arytenoidei interni may be paralysed, on one or both sides, as a consequence of laryngitis or of hysteria. According as the affection is bilateral or unilateral, there is aphonia or mere hoarseness.

During phonation the vocal cords are separated by an oval or elliptical space, and appear to be very thin and narrow, owing in all probability to deficient tension.

Paralysis of the External Tensors, the crico-

thyroid muscles, is unknown, apart from the results of paralysis of the superior laryngeal nerve.

Paralysis of the Arytenoides.—This is also commonly a result of hysteria or of laryngeal catarrh, and gives rise to hoarseness or aphonia. During phonation the cords meet in front, but are separated posteriorly by a triangular gap.

TREATMENT.—If the paralysed condition depend on serious disease outside the larynx, local treatment is of little avail. When syphilis or aneurysm is suspected, iodide of potassium should be prescribed freely. In cases of adductor paralysis, anæmia and the hysterical state must be suitably treated, and intra- or extra-laryngeal faradisation may be tried, but sudden recovery often occurs without any treatment. See PNEUMOGASTRIC NERVE, Diseases of.

6. Larynx, Spasm of.—In the description of other diseases of the larynx, this condition has been referred to as a frequent complication. Spasm causes the urgent symptoms when the larynx is irritated by the lodgment of a foreign body or the like. It may result from pressure on, or disease of, the pneumogastric or recurrent laryngeal nerve; from hysteria; or as a manifestation of a more general affection of the nervous system, in which case it constitutes the following special malady.

Laryngismus Stridulus.—SYNON.: Child-Crowing; Spasmodic Croup; False Croup: Fr. *Spasme de la Glotte*; *Pseudo-croup Nerveux*; Ger. *Kehlkopfkrampf*.

DEFINITION.—*Laryngismus stridulus* is characterised by short or more prolonged accessions of suffocation; depending on tonic spasm of the adductor muscles of the larynx, and usually of the diaphragm and other respiratory muscles, causing closure of the glottis and a sudden arrest of inspiration; and ending in a shrill crowing sound, as the inspiratory act is resumed and concluded. It is purely a nervous disease; is unaccompanied by any inflammatory affection of the larynx or air-passages; and is often associated with other convulsive affections.

ÆTIOLOGY.—Anything causing excessive reflex irritability, rickets, chronic hydrocephalus and other organic affections of the brain or medulla oblongata, predispose to this convulsive affection. It is sometimes associated with the irritation of teething. A sudden fright, irritation of the larynx by the accidental entrance of food, or some such slight agitation as that caused by a child being tossed in the air, may excite the attack.

SYMPTOMS.—With or without premonitory indications of a tendency to convulsive affection, such as drawing-in of the thumbs and great toes, or clenching of the hands; often during sleep, and with no evident exciting cause, or at any time in the day; a child is suddenly attacked with difficult breathing, inspiration being accompanied by the crowing sound characteristic of laryngeal spasm. This may continue for some time, and then gradually subside. The spasm may be short, or it may be longer and more intense, inspiration being proportionately difficult. It may be complete, and the act of inspiration cease entirely, until, just as death seems imminent, the spasm relaxes, and with a crowing inspiration breathing is re-established. In the worst cases, and sometimes in the first attack, death does actually occur.

DIAGNOSIS.—The diagnosis of this disease from laryngitis is considered under Acute Laryngitis.

The symptoms caused by a foreign body lodged in the larynx closely simulate laryngismus stridulus. The nature of the case is decided by its history; and, unless the age of the patient precludes it, by a laryngoscopic examination.

PROGNOSIS.—The milder forms of laryngismus stridulus yield to suitable treatment, and disappear as improvement takes place in the condition inducing the attack. Severer forms, if not fatal in a first, may be so in a subsequent attack. When the spasm depends on some incurable organic change in the nervous system, the case is of course hopeless from the first.

TREATMENT.—Attention to the diet and general management of the child, regular bathing, and the administration of remedies suitable to correct faults of digestion, are necessary (see RICKETS). The persevering use of bromide of potassium has been found beneficial; and chloral hydrate is of undoubted value. For the immediate treatment of the spasmodic attack, prompt immersion in a warm bath, the administration of an emetic, or the use of an anæsthetic vapour or amyl nitrite may be resorted to; and should breathing not be re-established as the spasm ceases, dashing cold water on the face and chest, friction, application of strong ammonia or vinegar to the nostrils, and especially artificial respiration, must be adopted, with the object of restoring the respiratory function. Tracheotomy may be requisite, but the practitioner is, unfortunately, seldom present when the indications for the operation arise.

7. Larynx, Syphilis of.—Syphilis affects the larynx differently according to the stage of the disease at which the organ is attacked. Erythematous maculæ, raised mucous patches or condylomata, and superficial ulceration, like that seen in the fauces and pharynx, are described as secondary lesions, but are seldom actually observed, as opportunities for making a laryngoscopic examination are not often afforded. Mucous patches, represented by small greyish flat elevations, and congestion, are the commonest manifestations at this period of the disease. These patches generally disappear without leaving any trace of their existence.

The larynx is more seriously affected in advanced stages of syphilis. The lesions, consisting of diffuse infiltration, nodular gummatous deposits, or ulceration, are especially prone to attack the epiglottis and vocal cords, and in a less degree the ventricular bands and posterior wall.

The special proclivity of the epiglottis to syphilitic disease has been attributed to direct infection from the pharynx, it being an undoubted fact that syphilis generally involves the pharynx together with the larynx. Syphilitic ulceration may be superficial or deep. Deep ulcers, which are often of gummatous origin, are sharply cut, and extend rapidly. As a result, extensive destruction of the epiglottis, suppurative perichondritis, and necrosis of the various cartilages, often ensue. External fistulæ are occasionally thus produced. Perichondritis at times develops without previous ulceration. Cicatrices are almost an invariable sequel of deep ulceration, and are a great source of danger, owing to the contraction and stenosis which they occasion. Curious puckering of different parts is commonly produced, at times associated with small polypoid excrescences of the mucous membrane. These last, unlike gummata, show no tendency to ulcerate, and may gradually disappear. Adhesion and webbing

of the cords, adhesion of the epiglottis to the walls of the pharynx, fixation of the vocal cords in various positions, sometimes simulating bilateral abductor palsy, and depending then on fibrous changes around the crico-arytenoid articulations—these are some of the many effects of syphilitic cicatrisation.

In *hereditary* syphilis, lesions of the larynx generally occur within the first few months after birth, but occasionally the larynx is not attacked before the age of puberty is reached. The early manifestations of the disease in hereditary cases are represented by congestion and mucous patches; at a later period they are not to be distinguished from those which occur in the advanced stage of acquired syphilis. Deep ulceration in any case may be associated with extensive oedematous swelling, and hæmorrhage from perforation of large vessels is an occasional occurrence.

SYMPTOMS.—Secondary syphilitic affections cause hoarseness and sometimes loss of voice, but there is usually neither pain, cough, fever, nor dyspnoea. The more serious tertiary affections may give rise to all the symptoms caused by tubercular ulceration, but pain and dysphagia are rarely experienced except when the epiglottis is extensively ulcerated, and even then these symptoms are less severe than in tubercular cases, and the constitutional symptoms are those of syphilis, as distinguished from consumption.

DIAGNOSIS.—Secondary syphilitic affections of the larynx are easily recognised with the laryngoscope, and there are usually other indications of the constitutional taint. The diagnosis of the disease, in its later stages, must be based on the appearance of the lesions above mentioned, combined with manifestations of syphilis in other parts of the body, especially of the skin and pharynx. In the absence of constitutional symptoms, the diagnosis may present great difficulties, especially as regards tuberculous. This question will be discussed in the next section.

It is sometimes not altogether easy to distinguish syphilitic from carcinomatous ulceration, but in the latter disease the appearance of a growth is more pronounced, ulceration is less rapid, and pain is more often present. Moreover, the vocal cords and ventricular bands are the favourite seats of malignant growths, the epiglottis and other parts being seldom primarily affected.

The good results following the use of iodide of potassium will often assist in arriving at a correct diagnosis, but this test is open to a fallacy, as carcinoma and syphilis may co-exist.

PROGNOSIS.—The prognosis in cases of laryngeal syphilis must vary according to its form. In early cases, and where ulceration is superficial, the prognosis is very favourable, but in advanced stages the prospects of the patient are more uncertain; for, although the progress of ulceration can almost invariably be arrested by treatment, subsequent cicatrisation may cause dangerous stenosis. A knowledge of the complications incidental to deep ulceration should induce us always to give a guarded opinion.

TREATMENT.—Local treatment is not necessary for the secondary syphilitic affections of the larynx, and we must trust to mercurial inunction and other constitutional remedies. Syphilitic ulceration of the larynx requires persevering treatment with large doses of iodide of potassium; and where it does not yield to this remedy, appropriately combined with quinine, cod-liver oil, &c., mercury must be

employed, the best method being by mercurial inunction or the hypodermic injection of the perchloride. A combination of mercury and iodide of potassium is often useful. The local application of a solution consisting of iodine 10 grs., iodide of potassium 100 grs., glycerine 1 oz., is sometimes of service in the case of syphilitic ulcers, in addition to the above treatment. When the dyspnoea is dangerous, tracheotomy must not be delayed. It will usually prove successful, although the destruction of tissue and cicatrisation may be such as to necessitate the permanent wearing of the tube. Operations for the division of cicatricial bands and adhesions seldom give satisfactory results, owing to the tendency of the parts to unite again. Systematic dilatation, by means of Schröter's hollow vulcanite bougies, may be tried in such cases.

8. Larynx, Tuberculosis of. — **SYNON.:** Laryngeal Phthisis; *Fr. Phthisie Laryngée*; *Ger. Kehlkopf-tuberculose.*

ÆTIOLOGY.—Laryngeal tuberculosis is almost invariably secondary to pulmonary phthisis, but in a few instances a necropsy has demonstrated the existence of tubercular disease in the larynx without any affection of the lung. In the former case the larynx is either directly inoculated with infective sputum derived from the lung, which is the usual method, or the tubercular virus is conveyed to the larynx by the blood. Where the larynx is primarily affected, we may suppose that the infective agent, the tubercle-bacillus, is inhaled, and effects a lodgment here without reaching the lung.

ANATOMICAL CHARACTERS.—In the larynx, as in other mucous membranes, the tubercular process may be considered under two heads—infiltration or deposit, and ulceration; but inasmuch as the necrotic element predominates over the fibrous or indurative, the tendency is ultimately towards ulceration. The degree of infiltration varies greatly, now giving rise to massive swelling of parts like the epiglottis and aryteno-epiglottic folds, where the submucous tissue is loosely arranged, at other times merely extending to the subepithelial layer. In the latter case, owing to the early development of ulceration, a stage of infiltration cannot generally be seen to precede loss of substance, though from analogy there is reason to believe that this is invariably the case. Definite tubercular tumours are occasionally met with.

The parts most prone to tubercular disease may be thus enumerated, in the order of frequency: the vocal cords and inter-arytenoid fold in about equal proportions, the aryteno-epiglottic folds, epiglottis, and, lastly, the ventricular bands. Extension of the infiltration and ulceration to the deeper parts may lead to suppurative or adhesive perichondritis, especially of the arytenoid cartilages. Suppurative perichondritis causes necrosis, and at times extrusion of the cartilage. Oedema is a frequent complication of extensive tubercular lesions. It is unnecessary in the present article to describe the manifold changes that may be produced in different cases.

SYMPTOMS.—The symptoms of this affection are those of an aggravated laryngitis: hoarseness or aphonia, irritable cough, difficulty or pain in swallowing when the epiglottis or aryteno-epiglottic folds are involved, and inspiratory dyspnoea and stridor if stenosis be present. Pain shooting to the ear is occasionally complained of, and is probably referred from the sensory nerve of the larynx, the

superior laryngeal, to the auricular branch of the vagus. The constitutional and local symptoms of pulmonary phthisis, which are present in varying degrees, add much to the patient's distress. In early cases the laryngoscope reveals small shallow ulcers or pale granulations on the vocal cords, particularly their posterior ends, fleshy swelling of one or both cords, and prominence of the inter-arytænoïd fold, often with an irregular papillary margin. Swelling of one or both sides of the epiglottis, aryteno-epiglottic folds, and ventricular bands, and deep ulceration may be observed later on. The ulcers present either a greyish-yellow or pinkish granular base, and minute yellowish nodules are occasionally developed in their neighbourhood. In certain instances the vocal cords are split longitudinally into terrace-like, reddish, ulcerated ridges, so that each cord seems to be composed of several individual segments. Small tubercular tumours, of a greyish-pink colour, may occasionally be seen springing from the cords, ventricles, ventricular bands, or other parts. When the epiglottis is much swollen or hangs backwards, it may be impossible to obtain a view of the rest of the larynx. A similar difficulty is sometimes experienced when the larynx is coated with a copious viscid secretion. The colour of the larynx varies greatly: generally speaking, a greyish-pink or pale yellowish tint prevails, contrasting often with localised patches of congestion in the vicinity of ulcers or infiltrations. But this colour, which is very characteristic, is not invariably met with, and general congestion may exist. Impaired mobility of the cords is very common; it mostly depends on mechanical fixation of the arytenoid cartilages from surrounding infiltration. At times the vocal cords occupy the median position, simulating bilateral abductor paralysis, and giving rise to severe stenosis. Neuropathic paralysis also occurs. Thus one cord may be motionless in the cadaveric position, midway between that of adduction and abduction. On the right side this condition may occasionally be the result of implication of the recurrent laryngeal nerve in pleuritic thickening of the apex of the right lung; whereas the left recurrent may be compressed by enlarged bronchial glands as it winds round the arch of the aorta. Imperfect closure of the glottis depending on bilateral paresis of the adductors, as in cases of functional or hysterical paralysis, is a more common appearance. Lastly, in advanced cases of phthisis, aphonia may be unassociated with any defect of movement, the feeble action of the respiratory muscles being insufficient to cause the requisite vibration of the cords. In other instances paralysis is probably of myopathic origin.

DIAGNOSIS.—Chronic laryngitis is sometimes one of the earliest symptoms of phthisis, and therefore should always direct attention to the state of the lungs. The diagnosis of tubercular disease rests on the detection of localised infiltration or ulceration of certain parts of the larynx, in association with physical signs of pulmonary tuberculosis. Syphilis is the disease with which it is most likely to be confounded, and the difficulty is increased by the fact that the two affections may co-exist; some authors even assert that syphilitic ulceration predisposes to tuberculosis. Pronounced pallor of the larynx, swelling of the inter-arytænoïd folds, with papillary excrescences, fleshy swelling of one cord, chronic ulcers of the cords, and a pale swollen condition of the aryteno-epiglottic folds and epiglottis,

are very characteristic of tuberculosis. On the other hand, marked congestion, rapidly extending ulceration of the cords or epiglottis, and cicatricial contraction, would be in favour of syphilis. Nevertheless, in many cases the laryngoscopic appearances are quite inconclusive; and, should examination of the lungs yield a negative or equivocal result, the detection of the tubercle-bacillus in the sputum will alone establish the diagnosis. Tuberculosis can seldom be mistaken for a malignant growth, but the diagnosis will be considered under the latter disease.

PROGNOSIS.—Laryngeal tuberculosis is rarely cured, though spontaneous cicatrization undoubtedly occurs in exceptional cases. The progress of the disease can often be temporarily checked, and at times is arrested by suitable treatment. As a rule, however, the prognosis is most unfavourable. Infiltration of the epiglottis and aryteno-epiglottic folds has a most ominous significance, owing to the interference with deglutition thereby entailed.

TREATMENT.—The constitutional treatment is discussed in the article on PHTHISIS; consequently the local treatment alone will be considered here. Lactic acid is the most efficacious remedy at present known. The writer has seen several cases where permanent cicatrization of tubercular ulcers has followed the systematic application of this remedy. The larynx must first be well brushed out with a 20-per-cent. solution of cocaine; and then, after an interval of three to five minutes, a 50-per-cent. solution of the acid should be thoroughly applied on a small piece of cotton wool, fixed to the screw of a laryngeal holder. The strength of the solution should be increased till saturation is reached, and the treatment should be continued for ten days to a fortnight, the applications being made every other day, or in some cases daily. It is extremely important to paint the larynx thoroughly with cocaine two or three times before using the acid, otherwise the application is very painful. If, notwithstanding this precaution, pain be experienced, a weak spray of cocaine to the larynx may be trusted to give relief. The selection of fit cases is a matter of great moment. Real benefit is only to be expected where localised ulceration is unassociated with much submucous thickening. Where deep infiltration exists, radical treatment is out of the question.

A solution of menthol in olive oil, 20 per cent., painted on the larynx, gives much relief to pain and dysphagia, and is said to promote healing of ulcers; but in the last respect it cannot be compared with lactic acid. Insufflation of a powder consisting of boric acid and iodoform equal parts, with cocaine or morphine $\frac{1}{6}$ to $\frac{1}{3}$ of a grain, has also been much praised, but its effects are only palliative.

Painful deglutition can generally be relieved by spraying the throat, a few minutes before food is taken, with a 2- to 5-per-cent. solution of cocaine. A lozenge, containing $\frac{1}{10}$ to $\frac{1}{6}$ of a grain of cocaine, also gives relief in less severe cases. Insufflation of morphine, $\frac{1}{6}$ of a grain, with a little starch-powder or sugar of milk, produces less complete analgesia, but the effect lasts rather longer. Much relief may also be obtained from insufflation of 'new orthoform.'

In cases where liquids enter the larynx during drinking, as sometimes happens when the epiglottis is destroyed, Wolfenden recommends that the patient should drink through a tube, lying flat on

his face. Thickened drinks can often be taken better than ordinary fluids in such cases. Laryngeal cough may be mitigated by a cocaine-spray, the use of menthol or oil of peppermint in an oro-nasal respirator, insufflations of morphine, or by sucking ice.

Tracheotomy is only to be performed when marked stenosis is produced; but this operation is seldom required, and its effects on the pulmonary disease are very unfavourable, on account of the difficulty of expectoration which is experienced when the action of the glottis is abolished by the introduction of a tracheal cannula.

9. Larynx, Tumours of.—(a) **Benign.** SYNON.: Polypi, or Growths of the Larynx; Fr. *Tumeurs, Kystes, et Polypes du Larynx*; Ger. *Kehlkopfpolypen*.

ETIOLOGY.—The invention and use of the laryngoscope, leading to accurate diagnosis, has established the fact that tumours of the larynx are of much more frequent occurrence than was formerly supposed. They are most common in adult males, but they occur in either sex, and at any age from infancy upwards. Inflammatory attacks, syphilis, and anything leading to habitual congestion of the larynx, are said to favour their development.

ANATOMICAL CHARACTERS.—Growths of various kinds occur in the larynx, papillomata being much the commonest. These present the appearance of a sessile warty or mulberry-like growth, attached generally to the anterior part of the vocal cords, though they may spring from almost any part of the larynx. Papillomata vary in size from a millet-seed to a walnut, and may be single or multiple. They sometimes show a tendency to recur when removed. Fibromata, the next commonest form of innocent tumour, may be sessile or pedunculated; their surface is usually smooth or slightly lobulated, but in size and localisation they closely resemble papillomata.

All other benign growths are very rare, and it must suffice to enumerate myxoma, lipoma, enchondroma, adenoma, angioma, and cystic tumour.

SYMPTOMS.—Benign tumours may cause little inconvenience; but, owing to the fact that the commoner varieties generally affect the vocal cords, some modification of the voice is almost a constant symptom. A dry spasmodic or croupy cough is sometimes excited. The breathing is but little affected until the growth attains some size, when dyspnoea will set in, at first only on exertion, occasionally spasmodic; as the growth increases it becomes constant, and at last it may prove fatal if the disease be unrelieved. Tumours attached below the vocal cords are rare; when they exist, and are large enough to interfere with the breathing, expiration is as noisy and difficult as inspiration. These growths are usually painless. They may be so situated as to interfere with swallowing, but this is not usual. In addition to these symptoms, the growth can be seen with the aid of the laryngoscope, and felt with the laryngeal probe or sound, and sometimes with the finger. Occasionally portions of a papilloma are expelled by coughing.

DIAGNOSIS.—A certain diagnosis can only be arrived at by examination of the larynx. The laryngoscope will often, but not invariably, enable us to distinguish a papilloma from a fibroma. The diagnosis of a benign from a malignant growth is sometimes no easy matter, though the absence of ulceration, congestion, or infiltration, which cha-

racterises an innocent tumour, is rare in malignant disease. The fact that simple growths hardly ever originate from the inter-arytenoid or aryteno-epiglottic folds will help to distinguish these from the polypoid excrescences that often fringe the margin of tubercular or syphilitic ulcers in these regions.

PROGNOSIS.—The importance of these growths varies with their situation and rate of increase. A few months have sufficed for the growth of tumours from their origin to their attaining a size sufficient to threaten suffocation; in other cases they may exist for years without giving rise to any symptom beyond dysphonia or aphonia. As soon as a growth causes dyspnoea it has become dangerous. The disease must practically be regarded as incurable, except by operation or other local treatment.

TREATMENT.—A small stationary fibroma or other tumour, giving rise to but little inconvenience, requires no treatment. All other tumours must be removed by operation. Removal may be effected by instruments introduced into the larynx from above with the aid of the laryngoscope; or, where the disease is very extensive, an artificial opening into the larynx (thyrotomy or division of both thyroid and cricoid) may be necessary, the growth or growths being removed through this opening. This is the only feasible method of operation in the case of children. If the growth is removed *per vias naturales*, it may be crushed through at its base by a properly constructed *éraseur*; it may be seized and torn off by forceps; or it may be cut off by knives or scissors. The particular operation, and the instruments to be used, must be determined by the circumstances of the case. The use of a cocaine-spray renders such manipulations much easier. The statement which has been advanced, that the irritation of endo-laryngeal operations may induce the transformation of innocent into malignant growths, has been conclusively disproved.

Pachydermia Laryngis.—In this affection local thickening of the epithelium and subepithelial tissue gives rise to the appearance of small growths. Pachydermia attacks the vocal cords as a rule, but the inter-arytenoid fold at times is involved. In the former position the disease appears as a flattish papillomatous growth on the processus vocalis. When the change is symmetrical, as is often the case, the outgrowth on one side commonly fits into a corresponding shallow depression on the surface of the opposite growth. This appearance is believed to be the result of pressure.

Hoarseness and slight alterations of the voice may soon attract the patient's notice, or there may be no symptoms for some time. The diagnosis is generally easy when the vocal cords are affected. Carcinoma is the only disease that is likely to give trouble. But in carcinoma the growth is unilateral, except in advanced stages, and partial fixation of the cord occurs early, whereas in pachydermia the disease tends to become symmetrical, and the movements of the cords are seldom impaired. The progress of the two affections is very different. Carcinoma is progressive; pachydermia is more or less stationary and may completely disappear, though it may recur subsequently.

Pachydermia of the inter-arytenoid fold may closely simulate tuberculosis, but examination of the lungs and sputum will help to establish the diagnosis.

As regards treatment, the continued administra-

tion of iodide of potassium is believed by Semon and others to give good results. In obstinate cases the cautious use of the galvanic cautery has occasionally been successful.

(b) **Malignant.**—Malignant tumours of the larynx may be primary or secondary. Primary growths are far less rare than was formerly thought, carcinoma being much more often met with than sarcoma. Epithelioma is the commonest form of carcinoma, the medullary and scirrhous varieties occurring less frequently. Carcinoma develops as a 'cauliflower' or nodular growth from the vocal cords or ventricular bands, though occasionally other parts are first affected. The tumour, at first localised, tends gradually to involve the whole of one side or more of the larynx. Owing to the infiltrating nature of the disease, the mobility of the corresponding vocal cord is often interfered with. Ulceration is a common occurrence, and may be followed by oedema, hæmorrhage, perichondritis, and necrosis of the cartilages. Carcinoma sometimes shows little tendency to infect the glands and other parts of the body, and sarcoma is even less liable to spread.

SYMPTOMS.—Hoarseness or aphonia is usually the first symptom, but dysphagia and dyspnoea may arise later on. Pain is more pronounced in this than in any other affection of the larynx, and may shoot to the ear. Ulceration is sometimes attended with great fetor of the breath.

DIAGNOSIS.—The laryngoscopic appearances are seldom characteristic, often closely resembling those presented by innocent growths, especially papillomata. The diagnostic importance of fixation of the corresponding vocal cord has been pointed out by Semon. Microscopical evidence of carcinoma or sarcoma may sometimes be detected in small portions of the tumour, removed by the laryngeal forceps, and is then of course conclusive.

The diagnosis of syphilis from malignant disease has been already discussed. Tubercular lesions seldom present the appearance of a localised growth, and careful examination of the lungs and sputum will generally decide the matter. The age of the patient is of some importance, carcinoma being seldom observed before the age of forty.

PROGNOSIS.—The prognosis is unfavourable in all forms of carcinoma, but progress is least rapid in the scirrhous type. Sarcoma of the larynx seems to extend still more slowly.

TREATMENT.—Partial resection of the larynx has been successful in a few cases of early localised malignant disease, and is the only radical method that seems at present justifiable. Removal of a cancerous larynx was first practised by Billroth, and has since been performed by several Continental surgeons. The results of the operation have, however, been so unfavourable that it cannot be recommended. The obstruction to respiration may demand the performance of tracheotomy; and if the lower part of the trachea is free from disease, the operation will prolong life. Extirpation of a malignant growth by an endo-laryngeal operation should not be attempted.

Pain and dysphagia must be alleviated by the application of cocaine or morphine, as in cases of tuberculosis.

PERCY KIDD.

LATAH.—See ECSTASY.

LATERAL SCLEROSIS.—See SPINAL CORD.

LATHYRISM.—A condition somewhat analogous to ergotism and pellagra, believed to be due to a diet containing the *Lathyrus sativus* and *Lathyrus cicera*, two species of the chickpea, without a sufficiency of ordinary food.

The symptoms are muscular weakness, stiffness, and tremor, especially of the lower extremities, resulting in a peculiar ataxic gait; sensations of 'creeping' and various other paræsthesiæ; exaggerated deep reflexes, and occasionally disorders of the sexual reflex and of micturition and of defæcation. The symptoms develop fully in the course of a month, and disappear gradually if the cause be removed.

LAVAGE (Fr.).—SYNON.: Ger. *Magenauspülung*.

DEFINITION.—A method of washing out the stomach, introduced by Kussmaul.

DESCRIPTION.—The following apparatus is necessary:—(1) A soft flexible india-rubber stomach-tube, about twenty inches in length; (2) a large-sized glass funnel; (3) a yard of india-rubber tubing; and (4) some suitable lubricating material.

One end of the india-rubber tubing is fitted over the end of the glass funnel, and the other is attached to the stomach-tube by the insertion of a small piece of glass tubing, so that the observer can determine when the irrigation is complete by noticing that the returning fluid is quite clear. Two good-sized lateral oval openings should be made in the stomach-tube close to its rounded distal end.

Having moistened the tube with warm water, the practitioner introduces it into the pharynx with his right hand, and gently presses it down, while the patient, who is preferably in the sitting posture, performs the act of swallowing.

To wash out the stomach it is necessary to fill the receiver with fluid, to raise it to the level of the patient's head, and then to add more fluid until the whole of the apparatus is filled. A siphon-action should now be established by depressing the funnel, and the stomach is thus emptied. By repeatedly filling and emptying it as described, it can be thoroughly washed out. In withdrawing the tube it is advisable to pinch it so as to prevent reflux into the larynx. The repugnance some patients have to the use of the tube is generally soon overcome, and with a little practice a patient can acquire sufficient manipulative skill to introduce the tube and wash out his own stomach.

The fluid to be employed in lavage may be either lukewarm water; 1-per-cent. salt-solution; 3- to 5-per-cent. solution of bicarbonate of sodium; 3-per-cent. solution of either boric acid or borax; Vichy Water; or any innocuous fluid possessing antiseptic properties.

In the beginning, lavage may be resorted to once or twice daily, but less frequently as the case improves.

USES.—Lavage is of great service in removing fermenting gastric contents, in cleansing the gastric mucous membrane, and in stimulating the activity of the gastric glands in cases of chronic dyspepsia, especially when associated with excessive secretion of mucus. By its employment we may also increase peristaltic action, and strengthen the enfeebled gastric muscular fibres in cases of insufficiency or atony.

Among the diseases in which lavage has been

successfully employed may be mentioned gastric dilatation ; chronic gastritis ; and intractable cases of chronic dyspepsia. See STOMACH, Diseases of.

It should be remembered that there are certain possible dangers in connection with lavage. The chief of these is injury to the œsophagus or to the gastric walls, with hæmorrhage or perforation. In very rare instances fatal syncope has attended its use. Lavage should never be resorted to in cases of recent hæmatemesis, thoracic aneurysm, gastric ulcer, or advanced pulmonary and cardiovascular disease. The gastric contents should always be examined after they are withdrawn. See STOMACH, Examination of. JOHN HAROLD.

LEAD, Poisoning by.—SYNON. : Plumbism, Saturnism ; Fr. *Intoxication Saturnine* ; Ger. *Bleivergiftung*.

ÆTIOLOGY.—Pure metallic lead has probably no injurious action on the system, but it readily oxidises and forms salts, all of which are poisonous. The fume of the molten metal is composed of the oxide and sulphate of lead, and is so destructive to vegetable and animal life that at lead-smelting works very long flues and high chimneys are built for its removal. The length of the flue allows of the dust being deposited and recovered. Cleaning out of the flue is a dangerous process, and workmen are only allowed inside two hours at a time.

Although lead-salts are undoubtedly poisonous, they are not actively so ; hence *acute* lead-poisoning is extremely rare. A few cases of mild irritant-poisoning have occurred due to the ingestion of large doses of acetate of lead, and cases of acute saturnine encephalopathy have been produced by diachylon (plaster) taken as an abortifacient.

It is with the *chronic* form of poisoning that we have principally to deal ; and as lead is widely employed in the arts and manufactures, and food and drink are frequently contaminated by it, this form of poisoning, often very insidious in its development, may arise under various, and at times unexpected, circumstances.

1. Metallic Lead.—In Great Britain lead-poisoning can scarcely be said to occur among lead-miners, but in Australia where the ore exists largely as a carbonate, plumbism of even the worst type is not unknown. Men who smelt the ore and convert it into pig-lead, workers in lead or its alloys, such as plumbers, solderers, type-founders, and compositors, suffer. Saturnine poisoning too occurs among fishmongers from the metallic coating on their counters, in leather-cutters working on a leaden slab, and in file-makers. Young people engaged in placing leaden capsules on the necks of bottles containing spices &c. have suffered. Ill-defined and sometimes serious symptoms have followed the use of tea wrapped in leaden foil, of snuff similarly enveloped, of canned foods and fruits owing to the action of the juices upon the solder, and of articles of drink contaminated by the employment of shot for cleaning bottles.

Drinking-water is a frequent source of lead-poisoning. Several families in a town or district may be affected at the same time owing to the water having taken up lead in its transit through leaden pipes or its storage in leaden cisterns. Pure water, even distilled water, acts upon lead in the presence of air, and a slightly soluble oxide of lead is formed. Carbonic acid, absorbed by the water from the atmosphere, precipitates part of the oxide as oxy-

carbonate, while the remainder is kept in solution by the free carbonic acid. It is difficult to obtain an absolutely pure drinking-water. It usually contains a trace of organic impurity. The presence of nitrates and nitrites is particularly dangerous, not only on account of their possible origin from sewage, but because their presence enables the water to dissolve more lead. Sulphates, phosphates, carbonates, and silicates in water form insoluble compounds with lead, and becoming deposited on the interior of the pipe form a protective covering. Yet even in these cases the presence of carbonic acid in the water may convert part of an insoluble lead-salt into one that is soluble. Peaty waters have a strong 'plumbo-solvency' as a rule. This has been attributed to the presence of an acid arising from vegetable decomposition. It is probable that the action of water upon lead is more than one of simple chemistry. Power attributed the 'plumbo-solvency' of peaty waters to the presence of two varieties of micro-organisms, and in a series of investigations on drinking-water carried out by Bolam, Mack, and the writer, it was found that while the solvency of water upon lead was influenced by the weather and the character of the salts dissolved in the water, it was frequently proportional to the number of micro-organisms contained therein. Water capable of producing this effect upon lead will to a considerable extent lose this power if filtered through layers of sand and magnesian limestone. It is desirable to change these filtering beds frequently. For the conduit of drinking-water into houses and its storage, galvanised iron and glass pipes have been recommended, and slate cisterns. These, however, are not without danger, for in the Colonies, where in consequence of long periods of drought the water has to be stored in galvanised iron cisterns, epidemics of plumbism have occurred owing to the molten zinc in which the iron plates were dipped having contained lead. Besides, even when cisterns are made of slate the slabs may be joined together by means of red or white lead.

Oxides of Lead.—Persons employed in the manufacture of red-lead, those who handle it or inhale the metallic dust frequently suffer. The writer has seen numerous severe cases of lead-poisoning in workmen engaged in the manufacture of the large galvanic batteries used for telegraph purposes, also in coloured-glass-makers, glass-polishers, and in dip-pers of cheap earthenware.

Salts of Lead.—The most important is the carbonate or white lead. The white-lead factories and the potteries have supplied the largest number of cases of plumbism. In Great Britain preference is shown by house-painters for lead carbonate made by the old Dutch process. The workpeople who empty the white beds in the factory, also those who wash and grind the white lead, frequently suffer from saturnine poisoning, but the part of the Dutch method of manufacture that is most dangerous is the emptying of the stoves or chambers wherein the washed carbonate of lead is dried. Although the stoves are not allowed to be emptied until the temperature has fallen, yet the inhalation of the very fine dust that rises from the shelves will in a few days, if this work is continued, be followed by serious, sometimes by fatal, results. This remark applies with equal force to certain departments of pottery-manufacture. A considerable proportion of earthenware manufactured in this country is

dipped in a glaze that contains a large percentage of white lead; hence the men who dip the ware, those who brush it afterwards or place it in the ovens, majolica-paintresses and litho-transfer-makers are especially prone to suffer from lead-poisoning. Plumbers, colour-mixers, and dye-workers who use chromate of lead run a similar risk. Women who wash the clothes of painters incur to some extent a like danger, as also those persons who use certain hair-dyes and cosmetics. See OCCUPATION-DISEASES.

Lead gains an entrance into the system by the alimentary canal, the respiratory passages, and the skin. Certain people exhibit an idiosyncrasy to lead, some being more readily affected by it than others. Women are more rapidly brought under the influence of lead than men, and are more seriously affected by it. Alcoholism, gout, and poverty predispose to plumbism.

SYMPTOMS.—Sooner or later after the introduction of lead into the system the individual gradually loses colour, his face becomes expressionless, and the skin exhibits a dull earthy hue. This is sometimes spoken of as *Saturnine cachexia*. The patient complains of an unpleasant taste in the mouth, and his breath is fetid. On attempting to show his teeth, which are usually discoloured, there is often considerable tremor of the muscles of the upper lip; the gums may be ulcerated, and at their margin close to the teeth there is usually seen a bluish or violet line, better marked as a rule on the lower than the upper gum, and not present where the teeth are absent. Ulceration and retraction of the gums cause the teeth in front to look elongated. This blue line is a valuable sign, not so much of active lead-poisoning as of the existence of lead in the tissues. The line is due to a deposition of particles of lead sulphide in the interior of large phagocytic cells lying in the layers beneath the epithelial covering of the gums; occasionally it also occurs in the epithelial cells themselves, and is usually most marked in the infiltrating cells present in large numbers at those points where the ulceration of the gum is most active.

Lead Colic.—**SYNON.**: *Colica Saturnina*; Fr. *Colique de Plomb*; Ger. *Bleikolik*.—One of the earliest symptoms complained of is pain in the abdomen, usually of a very severe character, and referred to the neighbourhood of the umbilicus. Pain may develop suddenly, and be so severe that the patient rolls about in agony. In most instances it is aggravated by pressure; in others, pain is relieved by pressure. It is often unilateral, worse in one half of the abdomen than the other. Pain, too, is often elicited in the neck by firm pressure applied along the course of the vagus. This pain is more acute on the side corresponding to that on which the abdominal pain is most severe. The abdominal wall is usually firm and retracted. There may be vomiting which fails to bring relief. Usually during the attack, and for some time previously, the bowels are obstinately constipated, but occasionally there is diarrhoea. In the attack the pulse may be hard and firm, showing heightened arterial tension, but when the pain is severe and continuous it is often extremely feeble and quick. There is distaste for food. The urine is extremely scanty, not more than six to eight ounces being passed daily. If it is a first attack of colic and the patient is young, the urine is generally free from albumen. Sleep is secured with difficulty. There

is a restlessness of body apparently in excess of that caused by the abdominal pain. In a few days, three to five under treatment, the severity of the colic subsides. Lead colic has been mistaken for appendicitis and *vice versa*.

Lead Palsy.—**SYNON.**: Fr. *Paralysie Saturnine*; Ger. *Bleilähmung*.—Following upon colic, but sometimes even without it, there develops motor paralysis. Wrist-drop is the commonest form of loss of power, and in this, as in all instances where paralysis is due to toxæmia, it is double, although it is frequently found worse on one side than the other. Muscular fatigue, the nature of patient's occupation, and the amount of local exposure determine to some extent, but not absolutely, the localisation of the loss of power. Wrist-drop occurs apart from working in lead, as for example by drinking contaminated water. It is symmetrical as well as bilateral. Usually it develops slowly, but the writer has known it occur in an hour or two. It is sometimes preceded by a sense of numbness and tingling. The loss of power is usually first observed in the common extensors of the fingers, and subsequently in those of the index, the little finger, thumb, the radial extensors of the wrist, ulnar, and short supinator. These muscles are not all equally involved, nor always in the order here mentioned. Paralysis of the extensors of the wrists, for example, may be more complete than that of the fingers. There may be too very pronounced paralysis of the wrists and fingers, and yet the patient may be able to extend his index finger. He may be unable to separate his fingers owing to paralysis of the dorsal interossei. The hand falls at a right angle to the forearm: it is flaccid and cannot be raised voluntarily. Any effort made to do so is followed by a considerable amount of muscular tremor, and by the unopposed flexor muscles being thrown into a state of contraction accompanied by irregular movements of such fingers as are not paralysed. While the distal phalanges of the fingers cannot be extended by the patient, he may succeed in raising them if the proximal are supported by the hand of the examiner. It is interesting to note that in wrist-drop the supinator longus, although innervated like the extensors by the musculo-spiral nerve, is not paralysed. This is the commonest form of saturnine palsy, but as other groups of muscles may be affected, it is customary to speak of types of lead-paralysis. In the *brachial* or *Duchenne-Erb* type the muscles involved are the deltoid, biceps, brachialis anticus, and supinator longus. This form of paralysis sometimes succeeds, at other times precedes, and is independent of wrist-drop. The arm becomes flaccid, and hangs powerless by the side in a semi-prone position. Elevation and rotation of the arm outwards are impossible, also flexion and supination of the forearm. In the *Aran-Duchenne* type the phenomena resemble those observed in progressive muscular atrophy. Not only are the thenar, hypothenar, and interosseous muscles of the hand paralysed, but they are also atrophied to a considerable extent; the interosseous grooves are deepened, and the hand presents a 'bird-claw' or a '*main en griffe*' appearance. Since this form of paralysis affects principally file-makers, who are in the habit of tightly gripping the chisel with the fingers of the left hand, it is thought that muscular strain plays a part in localising the paralysis. Bernhardt has published two cases of this form of

paralysis occurring in the right hand of house-painters, where the only muscular strain was that connected with the use of the brush. The muscles affected in the Aran-Duchenne type of saturnine paralysis do not exhibit marked tremor or fibrillation, nor, as a rule, does the lesion advance quickly; in these respects it differs from progressive muscular atrophy, which it otherwise closely resembles.

In lead-palsy the loss of muscular power is not confined to the arms and forearms; the muscles of the legs and trunk may become affected. In some of the writer's cases the muscles of the thighs, pelvis, and trunk were paralysed, and yet, despite this widespread implication of the muscular system, complete recovery took place. In the form of lead paralysis known as *peroneal*, which is usually consecutive to loss of power in the upper extremity, the common extensors of the toes and big toe are affected, while the muscles higher up the leg escape. There is ankle-drop. The foot falls in an inward direction, so that the patient tends to bear his weight upon the external border of the foot. It is seldom that the muscles of the face are affected, but those of the eyeball may be. Sensation, as a rule, is undisturbed, but the writer has observed analgesia. In saturnine paralysis the affected muscles when grasped may be tender, but the pain is never so acute as in alcoholic paralysis. The rapidity with which the palsied muscles atrophy causes recovery as a rule to be slow. Occasionally there is very marked tremor as well as atrophy of the affected muscles. The knee-jerks are often absent. Electrical contractility disappears in the paralysed muscles. It may even precede the loss of voluntary power, and be followed by the reaction of degeneration.

In the absence of a history of exposure to lead, and where no blue line is present in the gums, the diagnosis of saturnine paralysis is sometimes difficult. It might be mistaken for that caused by alcohol or arsenic. Saturnine paralysis usually appears first in the wrists and hands, while alcoholic and arsenical affect the legs below the knee. The muscles and nerves, too, are less tender. In progressive muscular atrophy the paralysis is secondary to the wasting, and the fibrillary tremor is usually of a finer character, and on the whole it is better marked in progressive muscular atrophy.

Other Phenomena.—Sometimes the symptoms of plumbism in female lead-workers assume an hysterical character. Beyond a few apparently insignificant nervous symptoms, usually of an exalted nature, the patient may not seem ill, and yet within the space of two days she may be dead. This form of toxic hysteria is often rapidly fatal. Lead has a particular selection for nervous tissues. White-lead workers often feel ill in the morning—they have headache and feel nervous. Occasionally, when in the factory, a worker, who, a short time previously, complained of severe headache, is observed suddenly to fall to the ground in a state of insensibility and is convulsed. The coma continues and the convulsions keep recurring, in one of which the patient perhaps dies, never having regained consciousness, or the epileptiform seizures pass off only for the patient to find, when he has recovered consciousness, that he has lost his eyesight. Vision may thus be lost temporarily or permanently even at a very early age. The writer has seen several young people, whose ages varied from 18 to 25 years, and who had

worked only a few months in a white-lead factory or a pottery, rendered blind for life. Neuro-retinitis may occur without previous epileptiform seizures. In addition to changes in the optic disc, ophthalmoscopic examination may reveal hæmorrhages in the retina. Acute delirium running on to mania may develop. The symptoms may resemble those of acute meningitis. There may be hemiplegia and aphasia. When the system has been exposed for a lengthened period to the influence of lead, albumen is generally found in the urine. Some authors attribute the epileptiform seizures and blindness to the diseased condition of the kidneys, but in the experience of the writer, while these are frequently associated, fatal saturnine encephalopathy may occur without albumen ever being present in the urine. The association of lead-poisoning and gout is well known. The one predisposes to the other. Women who are the subjects of lead-intoxication often suffer from menorrhagia, seldom amenorrhœa, and, if pregnant, very frequently miscarry. Lead is a strong ecboic. It is almost impossible for a pregnant female lead-worker, who may even not have any symptoms of plumbism, to continue following her occupation without aborting. Miscarriages follow in rapid succession, and many female lead-workers only succeed in bringing forth a living child at full term by withdrawing entirely from their work as soon as they know they are pregnant.

ANATOMICAL CHARACTERS.—A patient may die in acute saturnine encephalopathy, and the autopsy reveal very little naked-eye change. The brain may be dry and shrunken, or its veins congested; the tissue may be pale and watery as in uræmia, or there may be signs of meningitis if the disease has been of long standing. In chronic cases of lead-poisoning the kidneys are contracted, and, on microscopical examination, show a marked increase of the interstitial tissue. This change has come to be regarded as typical of all cases of lead-poisoning. This is scarcely quite correct. In the more acute cases the epithelial cells of the tubules are affected, and apart from the microscopical demonstration of this circumstance, there is also the fact that even in chronic lead-poisoning, although the kidney is contracted and its capsule adherent, the renal tissue is pale, indicating that the kidney was previously enlarged and pale. Owing to the intemperate habits of many lead-workers who die in infirmaries, it is sometimes difficult to say how much of the structural changes in the kidney is due to alcoholism and how much to plumbism. Upon the hæmoglobin of the red blood-cells lead is known to exercise an injurious influence. The action may be direct or indirect through its operation upon the marrow of the bones. Hence arise the anæmia and cachexia observed in the subjects of lead-poisoning—an anæmia which may be persistent. The iron of the broken-up hæmoglobin is eliminated by the skin and urine, and, after death, is found in excess in the liver.

Opinion is divided as to whether the paralysis caused by lead is due to peripheral neuritis or to changes in the central nervous system. While in the atrophied muscles the transverse striæ are found to have become diminished and the connective tissue increased, the nerves frequently exhibit signs of inflammation, viz. thickening of the sheath and increase of the connective tissue-elements, alterations of the medullary sheath, and atrophy of the axis-cylinder. In the subacute cases time has not been

partly by its action on the heart, partly by its dilating effect on the blood-vessels of the splanchnic area.

LEONTIASIS OSSEA.—See HYPERTROPHY, pp. 169 and 702.

LEPOTHRIX (λεπίς or λέπος, a scale; and θρίξ, a hair).—**DEFINITION.**—A term applied to a hair in which there is loosening and partial detachment of the overlapping edges of the scales of its cuticle.

Such hairs are usually met with in the axilla and scrotum; they are dull, dry, and lustreless. Diffuse or nodular masses of concretion encrust irregularly and adhere firmly to the hair. Glasgow Pattison and others have demonstrated the bacterial origin of this incrustation. The concretion on the hairs of the axilla is occasionally of a red colour (see SUDORIPAROUS GLANDS, Diseases of). The affected part should be shaved at frequent intervals and thoroughly cleansed by soap and water and parasiticide preparations.

JOHN HAROLD.

LEPROMA.—See LEPROSY.

LEPROSY (λεπρός, scaly).—**SYNON.** : Lepra; Elephantiasis Græcorum; Fr. *Lèpre*; Ger. *Der Aussatz*.

DEFINITION.—A specific disease, the result of infection by the *Bacillus lepræ*, running a chronic course and tending to a fatal issue. Its presence is characterised by granulomatous infiltration of the skin and mucous membranes, of certain nerve-trunks, and of the viscera, inducing functional irregularities and trophic changes in the affected parts.

GEOGRAPHICAL DISTRIBUTION.—It may be laid down as a general rule that lepers increase in numbers as the equator is approached from either pole. Although isolated cases may occur in any country of *Europe*, leprosy is practically confined, so far as that continent is concerned, to Western Norway, certain districts of the Baltic littoral, Southern Russia, Greece, and Turkey, and several of the islands of the Mediterranean, more especially Cyprus and Crete.

Asia.—From the coasts of Syria on the Mediterranean, right across Asia to the China Sea, leprosy is prevalent, and in many countries amounts to a scourge. Asia Minor, Persia, Turkestan, India, Burmah, and Southern China are mostly infected, the last-mentioned perhaps the most deeply of all. In the more northern latitudes of Asia, Siberia, Mongolia, Manchuria, Corea, and China north of the Yangtze, leprosy is rare or wholly unknown. In Russian Siberia there are one or two leper-settlements, but no general infection of the community. In Northern China and in Manchuria leprosy is not indigenous, and even in Corea the majority of lepers are Japanese. In India leprosy widely and generally prevails. The Annamese are extensively tainted, the dwellers in Cochín-China, Cambodia, and Siam less so.

The Islands of the Pacific.—Leprosy has been known in Japan from early times, and at the present day the disease is very prevalent. In almost every island in the Pacific infection by leprosy has followed the advent of the Chinese labourers.

The Islands of the Indian Ocean.—Ceylon and the Andaman Islands, Madagascar and Mauritius are all leprosy, infected probably from India; while Java, Sumatra, and Penang appear to have been infected by the Chinese.

Australasia.—The Chinese are accredited with introducing leprosy into Australia, and at the present time the majority of lepers are Chinese. Among the Maoris in New Zealand, however, leprosy would appear to be indigenous.

Africa.—Egypt has from the earliest recorded times been the seat of leprosy, and throughout the length and breadth of the African continent no people yet met with has been found free from the disease. Along the Mediterranean shores of Africa, in Morocco, in the Canary, Madeira, and St. Helena Islands, and wherever Europeans have penetrated on the East and West Coasts of the Dark Continent, leprosy is found to prevail. In South Africa so wide-spread is leprosy that a leper-asylum has been instituted at Robben Island, adjacent to Cape Town.

America.—In Canada, leprosy has occurred among Norwegian immigrants ever since they first settled in the country; the disease has, however, gained no marked hold on the inhabitants. In the United States the main seat of leprosy is among the Chinese on the Pacific slope, but among negroes and a few whites, mostly Norwegians, the disease also prevails. In Mexico and Central America lepers are to be seen in all the principal cities. In the West Indian Islands leprosy is frequently met with, chiefly among negroes. In South America, the Guiana States show the maximum of infection; and lepers are met with in every part of the continent except, it is stated, Chili and Bolivia.

LEPROSY AS IT AFFECTS RACES.—At the present moment the Teutonic stock, if we except the Norwegians, seem to be freer from leprosy both in Europe and North America than the Latin races whether they reside in Europe or South America. The whole Indo-European family has, however, at one time or other been leprosy, although at the present day the disease is abating to the westward, but still continues rife to the eastward, especially in Persia and India. The Mongolian family is by no means universally leprosy, the disease being confined mostly to Japan, Southern China, and places apparently infected from these sources.

ETIOLOGY.—Although leprosy can occur independently of any geological, geographical, or climatic conditions, there can be no doubt that a combination of overcrowding, poverty, and unwholesome food renders the individual especially susceptible to leprosy infection. The specific cause, however, is in all probability the *Bacillus lepræ*. Yet, although the bacillus so named is always associated with leprosy, our knowledge of the part it plays in leprosy is still incomplete. How leprosy is communicated from one person to another is unknown, and the disease has never been communicated to the lower animals.

Transmission by contagion.—The possibility of transmission by contagion is still in dispute. *In favour* of such a mode of transmission it may be urged:—that infected immigrants have contami-

nated leprosy-free communities; that leprosy can be communicated from husband to wife, from wife to husband, and from parent to offspring; that leprosy prevails in communities dwelling together in the close contact engendered by overcrowding; that isolation of lepers in an asylum or village is followed by a lessening, and it may be a disappearance, of the disease in the country in which such a step is adopted; and that leprosy has probably been communicated by both inoculation and vaccination. *Against* these arguments it may be maintained that most of the above contentions are open to some other explanation, e.g. the apparent origin of the disease among a reputedly leprosy-free people may be based on an inaccurate medical history of such community, while the cases of inoculation and of reputed communication of the disease by vaccination are too few to draw a definite conclusion from.

Heredity.—It is 'not proven' that leprosy is diffused by hereditary transmission. There is no leprosy physiognomy or physical trait to be noticed in the children of lepers; and when children, born of leprosy parents, are brought up (or suckled) by a leprosy mother, contagion cannot be excluded.

Sexual intercourse.—A single coitus is accredited by many men with the origin of their leprosy infection, but the evidence as to this method of acquiring leprosy is altogether faulty.

Food.—Jonathan Hutchinson maintains that uncooked and rotten fish is the medium by which leprosy is acquired. There is, however, no direct proof of this theory, which is based chiefly on the fact that leprosy disappeared from England (and elsewhere) as the food of the people improved. The scarcity of *salt* or of *rice*, to which some authorities ascribe leprosy, is probably only indicative of a general lack of food.

Vaccination.—Vaccination is not a factor of any great importance. Since vaccination was introduced into Canton, leprosy has actually diminished; and where there were previously two leper-villages, now only one exists. Among Europeans in leprosy countries calf-lymph, or lymph imported from Europe, is mostly used, so that the chance of white children contracting leprosy is infinitesimal. The question as to the presence of the *Bacillus lepræ* in vaccine-lymph obtained from leprosy persons has been tested in Trinidad and in India, where twenty-seven and ninety-three observations respectively were made on this subject, and, except in two doubtful cases, no bacilli were found.

The Bacillus Lepræ.—The parasite appertaining to leprosy may be demonstrated in the 'juice' expressed from a leprosy patch, in the discharge from a leprosy ulcer, and in sections of leprosy tissue. To obtain the 'juice,' a leprosy nodule is compressed between the blades of sinus- or nasal-forceps. The surface of the compressed part is then lightly pricked by multiple punctures, when a clear lymph-like fluid will quickly exude. Another plan of obtaining the 'juice' is to apply a small blister over a leprosy nodule. A smear of the juice on a cover-glass when dried and stained by Ziehl's or Ehrlich's method is first decolourised in 25 per cent. nitric acid for three minutes, then washed in 60 per cent. alcohol, and afterwards in distilled water. The specimen is then dried and mounted in xylol-balsam. When sections of tissue are examined, the same stains may be employed, but the preparation must be left in the stain for twenty minutes. After decolouration the preparation is dehydrated by absolute alcohol,

then immersed in oil of cloves and mounted in xylol-balsam. When thus prepared, the *Bacillus lepræ* will be found to present the appearance of a straight rod, measuring on an average 6μ by 3μ , and, if a contrast stain of methylene blue has been applied after decolouration by the acid, exhibiting bright red points in a blue setting. Vacuoles or uncoloured areas are observable in the stained bacilli; this appearance may, however, indicate the presence of stained 'granules' between unstained protoplasmic material. Spores are stated by some observers to be present, and others consider the parasite motile. These appearances vary with the stain employed; an aniline dye colouring the envelope so as to obscure the contents, whereas with such reagents as iodine, borax-methylene-blue, and osmic acid, the 'granules' colour deeply and the envelope is more transparent.

The *Bacillus lepræ* closely resembles the *Bacillus tuberculosis* in appearance and in behaviour. The differences and similarities are as follows: (1) The *Bacillus lepræ* is somewhat shorter, straighter, more uniform, and stains more readily than the *Bacillus tuberculosis*. (2) Cultivation and inoculation experiments with the *Bacillus lepræ* have all failed. (3) The bacilli in leprosy are found in groups or zooglææ, whether met with within the cells or in the lymphatics; whereas in tuberculosis the bacilli are found in comparatively small numbers, and in more scattered positions. (4) Leprosy selects the skin and nerves for attack, whereas tuberculosis specially affects the lungs and serous membranes.

INCUBATION OF LEPROSY.—There is neither clinical nor experimental evidence whereby even an approximate conclusion can be arrived at concerning the incubation-period of leprosy. Three to fifteen years have been suggested, but on quite unsatisfactory premises. Taking three years as the shortest period, it would explain how, disallowing heredity, leprosy is not met with in the children of lepers until the third year. According to Hoegh as many as twenty-seven years have passed between the time of presumed exposure and the invasion of the disease.

PREMONITORY SYMPTOMS.—There are no signs by which the subsequent development of the ordinary manifestations of leprosy can be foretold, although certain prodromata have been described. The principal of these are attacks of fever, weakness, hyperidrosis, dyspepsia and hepatic derangements, epistaxis, headache, vertigo, rheumatic pains, and various nervous affections such as hyperæsthesia and 'pins and needles.'

VARIETIES.—Although leprosy is a single disease, of a specific character, it presents a marked variability in its clinical features. So definitely do these types persist, that they have been regarded as independent morbid states. The types, however, in many instances blend, and what is termed 'mixed' leprosy results: a condition which tends to negative the idea of independency of the so-called nodular (or tuberculated) and the anæsthetic (or non-tuberculated) types of the disease.

Nodular Leprosy.—*SYNON.*: *Lepa Nodosa*, *L. Tuberculosa*, *L. Tuberculata*; Hypertrophic leprosy.

Prodromal phenomena may be pronounced, slightly marked, or practically absent. When present, especially in children, they consist of languor, drowsiness, profuse sweatings, a febrile state, epistaxis, enlarged glands, and change in the features

and in the character of the skin generally. It is not, however, until the characteristic cutaneous or nervous lesions gradually supervene that a person is known to be leprous.

The eruption.—On the face or ears, on the extremities, and less frequently on the trunk, erythematous-looking patches of various sizes appear during, or immediately after, a febrile attack. The patches, when first seen, consist of mere congestive areas, but the colour deepens until a reddish, bronzed, or coppery tint prevails. These coloured areas are thickened, slightly raised above the surrounding skin, and endowed with a primary hyperæsthesia which gives place, it may be speedily, to a state of impaired sensation. An approach at symmetry in the patches is usual, the two sides of the face or opposite limbs showing simultaneous eruptions, the former usually anticipating the latter. These leprous patches vary in area from the size of a shilling to several inches in diameter. With the subsidence of the feverishness the patient's general condition improves, the blotches on the skin fade and sometimes completely disappear. Traces, however, of the cutaneous lesions may remain in the form of a brownish tint here and there, and of a hardening, though but rarely of an elevation, of the skin. The subsidence of the primary eruption may be so complete as to give rise to a hope of a permanent cure, or to a belief that the diagnosis of leprosy was premature. In the course of a few weeks or months, however, there occurs another febrile attack associated with or followed by a fresh crop of discoloured patches not necessarily affecting the same areas of skin. These may again more or less completely fade away, or may leave patches which present a deep pigmentation and a hard infiltrated base. The second attack will be followed by others at irregular intervals, but it may not be until several such 'leprous storms' have come and gone that a permanent nodular thickening is left.

The second stage of nodular leprosy dates from the appearance of local deposits, which exist as raised masses of infiltration or 'nodules.' These nodular or tuberculated excrescences may be the first intimation that the illness is leprosy; for it occasionally happens that the febrile attacks and early cutaneous changes are unobserved or but slightly pronounced. The infiltrated patch, termed the *leproma*, may appear on the site of a previous macula or altogether independent of it. In consistency the lepromatous crop presents elevations which are at first firm and somewhat elastic. Their size varies, an infiltrated patch may cover an extensive area of skin, and the 'tubercles' may vary in size from that of a pea to a walnut, or even a pigeon's or hen's egg; the colour in white people is at first pink, changing to a deeper red, and finally to a dirty brown; in black races the leproma presents at first clear, rather transparent-looking, papules, which when pricked do not exude serum. The tumours may be discrete, aggregated, or they may coalesce. The skin over them looks coarse and greasy, and, when the elevations are decided, devoid of pain. Anæsthesia may obtain at first, but this usually gives way to normal sensation. Once more the disease may apparently subside, the lepromata becoming practically absorbed. On the other hand, several nodules may remain until another febrile attack ensues, when a fresh deposit takes place in the same or in previously unaffected regions of the skin. As crop succeeds crop with

recurrent attacks of fever, the skin of the face becomes permanently affected, and takes on the 'leonine' aspect so typical of nodular leprosy, a condition due to cutaneous and subcutaneous infiltration. Thickened masses cover the malar bones; the skin of the forehead protrudes, with deep lines between corresponding to the natural folds of the skin; the nose broadens; the eyelids look puffy; the chin appears hypertrophied; the ears enlarge, the nodules affecting the lobule and helix. On the limbs lepromatous nodules appear, especially on the backs of the hands and wrists and the outer aspects of the forearms. The dorsal aspects of the feet are favourite sites, but in this region they are more flattened as a rule than are the nodules on the hands. On any part of the limbs or trunk hyperplasia of the surface-tissues may develop with more or less symmetry, although the lepromatous eruptions on the back, on the front of the chest and abdomen, on the neck, on the palms and soles, are seldom pronounced. The skin over the shins, knees, and elbows tends to become harsh and scaly. Of the penile tissues the prepuce is most frequently attacked. Even the male nipple may become thickened. Although the hair of the scalp seldom falls, the hair elsewhere drops off, the eyebrows being early affected and lost. Coincidentally with the loss of hair the nails are lost or altered in appearance, remaining for a time as horny stumps.

Special Senses.—The eye usually shows destructive changes. Beginning usually with the infiltration of the conjunctiva, the leprous material may implicate the cornea, the iris, the ciliary body, the choroid, and the retina, usually in the order given. The eye may be, during the invasion, the seat of severe pain for a time, and finally the whole organ may be reduced to a mass of disorganised structures with total loss of sight. In some cases the eye bulks larger than normal, so that it is impossible for the eyelids to close. The nose is early attacked, the 'stiffness' of the nasal passages showing a hyperplasia of the mucous membrane; ultimately the cutaneous tissue thickens, the nose appears flattened, and the cartilages give way. The external ear exhibits thickened tissue almost from the onset of the disease, pendulous masses depending from the lobule, and the whole ear becomes stiffened and indurated. Hearing, however, although impaired at times, usually remains fairly good throughout the life of the leper.

The *mucous membranes.*—Deposits occur on the insides of the cheeks, on the fauces, in the epiglottidean folds, the vocal cords, and about the larynx, giving rise to huskiness of voice and changes in intonation.

The subsequent development of the nodules in leprosy varies: (1) the nodules may disappear after the subsidence of a febrile attack, leaving a cutaneous stain or deformity; (2) they may remain stationary or increase but slowly in size; (3) they may increase in size rapidly with each successive outburst of fever, the most recent adding to their bulk with each attack, the older becoming harder, denser, and smaller; (4) the nodules usually ulcerate sooner or later. These ulcers may heal, leaving cicatricial deformities; or they may extend and coalesce, so that a large area of a limb is involved, the granulations on the ulcer bleeding readily. Occasionally the ulcers become phagedenic, the parts attacked being rapidly destroyed.

Along with the local manifestations of leprosy,

constitutional symptoms co-exist. The febrile attacks are the most pronounced evidence of the general effect of the presence of the *B. lepræ*. The occurrence of fever is irregular as to its periods of recrudescence, the intervals between attacks varying from weeks to many months. The initial outbursts are usually shorter and sharper than those in the later stages, when the rise of temperature is more irregular and continues longer, rigors, sweating, and a morning and evening temperature of about 100° F. to 103° F. respectively being usual. During the apyrexial intervals the temperature remains continuously subnormal. Dyspepsia is a common feature of the ailment. The bodily strength remains for a time unimpaired, but gradually the vigour languishes, and in the later stages slight exertion is followed by exhaustion and prostration. A cough, at first laryngeal in origin, harasses the patient when the disease obtains a firm hold, and, finally, pulmonary tuberculosis usually supervenes and leads to a fatal issue. Instead of, or in addition to, pulmonary lesions, visceral changes, especially in the kidneys, are common features of the last stages of the leper's life. The average duration of life in nodular leprosy after the onset of the disease is from four to eight years. In the badly-cared-for two or three years may be the limit; but in the better-off class of lepers eight to twelve years of life may be expected.

B. Nerve-Leprosy. — *SYNON.* : Anæsthetic, Smooth, Non-tuberculated, Atrophic, Mutilating, or Dry Leprosy.

PRODROMATA.—Febrile attacks play little or no part in the precursory stage of anæsthetic leprosy, but in the course of the nerve-trunks and in their terminations pains of an indefinite character prevail, which at this stage of the ailment are usually put down to rheumatism or neuralgia. Occasional shooting pains in the nerves, with tenderness when the trunk is pressed upon, and a hyperæsthesia, or, it may be, a partial anæsthesia of certain patches of the skin, indicate some perversion of nerve-function. In the prodromal stage, also, weakness and even wasting of the muscles of the forearm may occur before it is possible to recognise leprosy as the cause.

Eruption.—Twelve months of prodromal symptoms may elapse before cutaneous signs develop; and as the skin-affections and the changes in the nerves and the general signs and symptoms alter as they progress, it is convenient to describe them under three stages:

The first or eruptive stage is characterised by the appearance of an eruption, by nerve-changes, and by commencing atrophy. The eruption consists of spots or blotchy discolouration in the skin. So indefinite is the alteration in the colour of the skin in the white and yellow races, that it is only in a particularly favourable light, or sometimes when viewed at some little distance from the patient, that the eruption can be seen at all. A pale or light yellow tinge in the fairer races, and a bright yellow hue in the darker races, appears on the skin in small discrete areas, possessing usually a circular outline. The spots seldom exceed an inch in diameter, they are only partially, if at all, anæsthetic, and are accompanied by itching or occasionally a burning sensation, especially when rubbed. No elevation attends the spots of eruption, and the margins merge into the surrounding skin. It is on the back, the extensor aspects of the upper or lower limbs, and less frequently on the face, that the

eruption first appears; the spots are for the most part symmetrical, and they frequently appear to develop along the course of a nerve-trunk. Concomitant with the eruption, changes can be made out in the nerve-trunks; and if attention is drawn to the nerves prior to the spots appearing, the tenderness and the increase in size in the nerve-trunks are found to have preceded the discolouration of the skin. Anæsthesia, however, is rare at this stage; but on the affected skin the secretion of sweat is arrested, tactile sensibility is partially in abeyance, and the muscular power is impaired, as evidenced by tremor, weakness, and feebleness of grasp. The first stage of nerve-leprosy may last for one, two, or more years.

The second or developing stage.—The affected patches of skin during this period of the disease show a serpiginous tendency, their edges being raised and scaly, and their surfaces becoming anæsthetic and wrinkled. The pallor or even whiteness of the centres of the patches is marked, the hair over them also becomes white before falling, and the secretion of sweat is completely suspended. Anæsthesia becomes a prominent feature; not only do the patches lose sensation, but the anæsthesia may extend on the upper extremities as high as the elbows and arms, and in the lower extremities to the knees and thighs. So complete is the anæsthesia that neither pricking nor pinching, heat nor cold, elicit any response; and the skin being devoid of feeling, accidental burns are common, causing wide and deep cicatrices on occasions. Bullæ appear on different parts of the body and limbs; they are usually quite small in the first stage of the disease, but later they may be of large size, several inches in diameter, appearing singly and quite suddenly. It is during the bullous eruption that fever and enlargement of lymphatic glands are met with in this variety of leprosy. The bullæ rupture a few days after formation, discharging a serous material which crusts and then falls off, leaving a pale, sharply defined, and anæsthetic patch. The coalescence of adjacent bullæ accounts for the rapid and serpiginous advance of anæsthetic patches on the skin. As time advances, the anæsthesia becomes deeper, the muscular strength wanes, the finger-pulps shrivel, the flexor tendons of the fingers (especially the fourth and fifth) contract, and the whole hand becomes deformed. The stages of change in the hand are usually as follows: Diminution of tactile sensibility, muscular weakness, contraction of tendons, wasting of the hand-muscles generally, atrophy of subcutaneous tissues, shrinking of the skin, absorption of the phalanges and dwindling of the hand. The nails become hard, contracted, clawed and pegged; the whole or part of a finger may drop off; or a dead piece of bone may be shed, and the nail may adhere to the second phalanx or to mere stumps projecting from the knuckles. Changes in the feet may also run more or less concurrently with those of the hand, perforating ulcers, œdema, and 'spontaneous amputation' of the toes by a process resembling that met with in *ainhum*, being common. With these changes the leper becomes weaker, thinner, and more apathetic; the nerve-trunks become thicker; and mutilation in the face, ears, and limbs proceeds apace. The patient's temperature is as a rule subnormal; or, while that of the extremities is much below normal, the trunk-temperature may be slightly raised.

The second stage may last for 6, 10, or more years.

The third or permanent stage.—A marked feature of this stage is the development of muscular paralysis. The third and seventh cranial nerves become affected, causing paralysis of the ocular and facial muscles; the affection attacking one or both sides. The muscles of the limbs are likewise paralysed, a fact specially noted during walking, the feet being lifted high and the limbs being swung or dragged along. Spontaneous amputation of the limbs may extend beyond the fingers and toes, and the wrist or ankle become the seat of separation; the part beyond the line of demarcation taking on a form of mummification in the upper extremity, but more often a moist form of gangrene in the lower extremity. During the third stage, the advance of the disease may be for a time arrested; and even a seeming accession of strength and sexual power may re-appear, and may continue for a time. The length of life of a leper suffering from anæsthetic leprosy is indefinite. Some lepers, if well cared for, may live for 20 to 30 or more years after developing the disease.

C. Mixed Leprosy.—When, in addition to the development of nodules in the skin and tissues, anæsthesia and thickening of the nerve-trunks occur, with some mutilation, the variety of leprosy is said to be ‘mixed.’

ANATOMICAL CHANGES.—The *Bacillus lepræ*, although the determining factor in leprosy changes, is not found generally distributed throughout the body. The presence of the bacillus in the blood has been both asserted and denied. In nerve-leprosy the bacilli are rarely found in the anæsthetic patches, in the fluid obtained by blisters over these patches, or in the pus flowing from the ulcers.

A section of a *cutaneous nodule* of some standing shows the epidermis to be attenuated, the true skin thickened and firmer than usual, and the subcutaneous tissues the seat of a diffuse infiltration. The walls of the blood-vessels, the nerve-sheaths, and the intraneural connective tissues are increased in bulk by the presence of a semi-gelatinous or lardaceous substance. The several glands of the skin, the papillæ, and the hair-follicles disappear in nodules of long standing. Microscopical examination of the nodules shows a marked infiltration of cells massed around the blood-vessels, the lymphatics, and the nerves. Giant-cells, laden with bacilli, may attain a size three or four times larger than a leucocyte. Bacilli are, in addition, often found in dense masses (globi) believed to be sections of lymphatic vessels stuffed with bacilli which have caused the coagulation of the lymph.

Neither in the sections of erythematous maculæ nor in those of anæsthetic patches are the bacilli usually met with, a diffuse fibroid degeneration with incomplete obliteration of the structures peculiar to the skin being the change most apparent in the latter. The nodules of the mucous membrane resemble in a general way those seen in the skin; they are, however, as might be expected, of a softer consistence.

The nerve-trunks in leprosy may attain a size three or four times larger than the normal. The swellings on the course of a nerve are not uniform, and the enlargements when cut into may appear of a pinkish, grey, or yellowish colour. The bundles of nerves are separated by the new-growth, the

nerve-tissue appears of an ashen-grey colour, and both the peri- and endo-neurium are infiltrated. The neurilemma itself and the axis-cylinder may degenerate, when the nerve becomes reduced to a mere fibrous cord. The nerves most frequently attacked are the ulnar, the median, the peroneal, the posterior tibial, and the branches of the superficial cervical plexus. Lesions of the spinal cord, such as sclerosis, meningitis, and changes in the posterior cornua, have been recorded in lepers, but they would seem to be exceptional, if indeed they are not altogether independent of leprosy infiltration. The liver, the spleen, the testes, and other organs may show typical leprosy cells in their tissues, although there are no macroscopical changes.

DIAGNOSIS.—The eruption or the development of anæsthetic patches on the skin is usually the first suspicious feature indicating a possibility of the disease being leprosy; and the discovery of the *Bacillus lepræ* in the ‘juices’ of the subcutaneous tissues or in the sheath of a nerve serves to clinch the diagnosis. Among a leprosy-infected people, syphilis, tuberculosis, ainhum, various forms of skin-diseases such as erythema, psoriasis, leucoderma, keloid, and several of the parasitic ailments of the skin are the more common diseases mistaken for leprosy. In regard to skin-affections their presence is apt to obscure the fact that leprosy is present; almost all the poorer lepers suffer from general scabies, and the macular patches are apt to be overlooked or altogether obscured by the eruptions due to scratching. When, however, anæsthesia is present, and the hair falls off; when, after a hypodermic injection of pilocarpine, patches of skin are found not to perspire; when the trunks of the nerves are found tender and thickened, and when the *Bacillus lepræ* is met with in the fluid of bullæ, &c., the diagnosis is established beyond doubt.

PROGNOSIS.—Although cases of leprosy are recorded, and perhaps proved, to have been ‘spontaneously’ cured, leprosy must be regarded generally as a disease from which recovery is impossible. The prognosis for nodular leprosy is highly unfavourable, and a fatal issue may be expected during any period from two to eight or ten years from the onset of the disease. An acute case may occasionally destroy life in a year or two, but it is more common for some intercurrent or super-vening ailment to develop, and carry off the patient. Bronchitis, pneumonia, pulmonary tuberculosis, or laryngeal constriction may attack the respiratory passages; Bright’s disease may hasten the end; or an intestinal flux, frequently of a dysenteric nature, may be the immediate cause of death.

A sufferer from nerve-leprosy is, however, in quite a different position from one afflicted with the nodular form of the disease; and the recorded cases of recovery are invariably of this variety of the disease. In these cases the activity of the bacillus seems to subside, and although the patient is left mutilated in various parts, the disease may cease to progress, and a long life of twenty to thirty or more years subsequent to the outbreak of the disease may be granted to the patient.

TREATMENT.—*Isolation.*—Although complete isolation of the leper is impossible, yet a modified system of segregation has, especially in Norway, seemed to do good. In India and China, leper-villages are plentiful, but they imply segregation in

a very limited sense, the lepers being free to come and go, beg in the streets, or sell the wares they have themselves manufactured. The general consensus of opinion is against lepers being allowed to beg or trade; more especially is this the case in the ulcerative stage of the disease, when the discharges from their skins, and it may be their respiratory and digestive tracts, are swarming with bacilli. It would seem, therefore, advisable that lepers should be isolated in asylums. Children born of lepers should be immediately removed from their surroundings and reared apart.

Hygienic and dietetic treatment.—A sufficiency of clothing and food, and good hygienic surroundings, serve to prolong the life of a person who has contracted leprosy. Cleanliness, avoidance of fatigue, and an open-air life, all aid materially in alleviating the virulence of the disease. So well recognised is this fact that many believe that, as in tuberculosis, so in leprosy, open-air treatment and all the dietetic and hygienic care that is bestowed with marked good in that disease will also alleviate, if not actually stay the progress of leprosy. In some hospitals the lepers are advised to come to the hospital twice yearly, when they are well fed, clothed and housed, and given cod-liver oil, iron, and other tonics with marked benefit. Under such treatment lepers improve temporarily, and it would appear that life may be prolonged indefinitely.

Medicinal.—Of the many 'cures' for leprosy which have been introduced none are in any sense specific. 'Chaulmoogra oil' and its active principle (*gynocardic acid*), taken internally in doses of from 10 to 40 minims of the oil thrice daily, and applied externally over the affected parts of the skin and joints, has some reputation as a curative agent. The oil may be introduced hypodermically. Gurjun oil, at one time highly spoken of, is now almost neglected. It is significant that in the district in which gurjun oil is produced—the Muar district of Johore—leprosy prevails widely. Cowti oil has been tried in Bombay. What is known as the Beaupterthuy treatment consists in supplying good food and general hygienic measures, in applying as a caustic the oil of the cashew nut, and in administering mercury and alkalis. Temporary improvement has followed this treatment. Arsenic in gradually increasing doses, perchloride of mercury by the mouth or hypodermically ($\frac{1}{2}$ grain weekly, Crocker), iodide of potassium in increasing doses, salicylate of sodium, salol, chlorate of potassium in doses of from 80 to 100 grains daily, have each and all been tried more or less extensively with seemingly good temporary effects. It must be remembered, however, that a leper under medicinal treatment is usually also under improved dietetic and hygienic surroundings, and it is difficult to differentiate between the beneficial effects of the purely medicinal and the hygienic measures. Unna has employed what may be termed 'reducing' remedies. The ointment he recommends for the body is: R Chrysarobin, 5 per cent.; salicylic acid, 2 per cent.; ichthyol, 5 per cent.; made with lanolin, or other vehicle, into an ointment for the skin and rubbed over the affected part once or twice daily. When the ointment is intended for the face pyrogallol is substituted for the chrysarobin.

Other remedies employed in leprosy are thyroid gland, methylene blue, aristol, euophen, naphthol, and resorcin, &c. Anti-venene has been tried in leprosy with apparent benefit. Leprine, an ex-

tract prepared from leprosy tissues, has also been employed, with indifferent results; and the hot-bath treatment of the Japanese has little to recommend it.

When for any reason a *surgical operation* is deemed necessary or expedient in a person suffering from leprosy, it may be unhesitatingly undertaken. Wounds in lepers heal readily. The removal of dead bone, amputation, nerve-stretching, the opening up of sinuses, operations on the eye, and tracheotomy, may all be hopefully undertaken for the relief of leper-patients whenever such operations are required. Perforating ulcers of the feet, a common ailment in leprosy, are perhaps best dealt with by passing a bistoury from the ulcer in the sole right through to the dorsum of the foot and carrying the knife forwards to emerge at the cleft between the toes; the wound thus made usually granulates up readily.

ROBERT LIVEING.

JAMES CANTLIE.

LEPTOMENINGITIS (λεπτός, delicate or thin; and *meningitis*).—A term signifying inflammation of the pia mater. See MENINGES, Diseases of.

LEPTOTHRIX (λεπτός, delicate or slender; and *θρίξ*, a filament or hair).—*Leptothrix buccalis* is a name assigned by Robin to certain vegetable parasites or minute filaments, which can be recognised, by means of the microscope, among the epithelial scales of the tongue or other parts of the mouth; and especially between the teeth, or in the hollows of decayed teeth. They occur in healthy persons, as well as in the sick, and have in this situation really no pathological signification.

Dermatologists also employ the term 'leptothrix' to indicate a morbid thinness and weakness of the hair.

LESION (λῆδο, I hurt).—This word originally signified a hurt or an injury; but its use is now extended to comprehend all organic changes of a morbid character, affecting an organ or tissue.

LETHARGY (λήθη, oblivion; and ἀργία, idleness).—A disorder of consciousness, which consists of prolonged and profound sleep, from which the patient may be momentarily aroused, but into which he falls off again immediately. One form of it corresponds with the final stage of hypnotism. See CONSCIOUSNESS, Disorders of; TRANCE; INSANITY (Mental Stupor); and NEGRO LETHARGY.

LEUCINE (λευκός, white).—SYNON.: Fr. *Leucine*; Ger. *Leucin*.

Leucine or amido-caproic acid is a decomposition-product of the complex proteid molecules, when these are acted upon by strong acids or alkalis, or when they are submitted to the prolonged action of the pancreatic ferment trypsin. It is a product of intestinal digestion, but does not occur normally in the fæces or urine.

It is now regarded as an antecedent of urea in the decomposition of proteids; the transformation in all probability occurring in the liver.

CHARACTERS.—Pure leucine is soluble in water, acids, and alkalis, slightly in alcohol, insoluble in ether. It sublimes without decomposition.

Microscopically, leucine, as it occurs in the urine, appears as oil-like, highly refracting, laminated, crystalline, globular masses, obscurely radiating; but, when pure, leucine forms white, refractile,

glistening, flat crystals (*see* URINARY DEPOSITS, *Coloured Plate*), having an unctuous feel. The microscopical test is not a thoroughly reliable one; hence we must have recourse to the following method: Free the urine of albuminous substances, and precipitate it with basic lead acetate; filter, and pass sulphuretted hydrogen gas through the filtrate to remove the excess of lead; filter, and evaporate the filtrate to dryness. Extract the residue with boiling alcohol; filter, and evaporate the filtrate to a syrupy consistence, when, if present, leucine will crystallise out.

Chemically, leucine is to be detected by the following reaction: A little urine mixed with nitric acid is carefully evaporated to dryness on platinum foil; a nearly imperceptible colourless residue is left. If caustic soda is added to this residue, and heat applied, the leucine will be dissolved, and according to its degree of purity the solution thus formed will be either colourless or of a yellowish-brown colour; and on concentrating the fluid by heat on platinum foil, an oily drop is formed, which rolls about on the surface of the foil (*Scherer's test*).

PATHOLOGICAL SIGNIFICANCE.—Leucine has been detected in nearly all the tissues of the body, more especially in the glandular tissues. It is found in the liver, kidneys, pancreas, the thymus, thyroid, salivary, and lymphatic glands, and in the brain. Leucine and Tyrosine have been detected in the urine only in cases of acute yellow atrophy of the liver, and in the atrophied hepatic cells in the same disease (*see* LIVER, Atrophy of, Acute Yellow). Tyrosine is invariably found associated with leucine. *See* TYROSINE.

JOHN HAROLD.

LEUCOCYTES.—*See* BLOOD, Morbid Conditions of.

LEUCOCYTHÆMIA (λευκός, white; κύτος, a cell, and αἷμα, blood).—**SYNON.**—*Leucæmia* (Virchow); *Fr. Leucocythémie*; *Ger. Leukämie*.

DEFINITION.—A disease, characterised by a considerable and persistent increase in the number of white corpuscles in the blood, associated with enlargement of the spleen and disease of the medulla of the bones, or with enlargement of the lymphatic glands.

Two varieties of the disease are now recognised: (1) *Spleno-medullary* (lieno-myelogenic) *leucocythæmia*, *myelocythæmia*, or *myelæmia*; characterised by enlargement of the spleen, by changes in the medulla of the bones, and by the presence of blood in which the increase of the white corpuscles is due chiefly to the unwonted presence of myelocytes, and to enormous numbers of polymorpho-nuclear granular leucocytes, of which an important proportion are eosinophile; and (2) *lymphatic leucocythæmia*, *lymphocythæmia*, or *lymphæmia*; characterised by enlargement of the lymphatic glands, and by blood in which the very numerous leucocytes consist almost entirely of lymphocytes (*p. 156*). It must be admitted that the two groups do not stand sharply apart from one another, since there may occur on the one hand cases of lymphocythæmia without any enlargement of the glands, and on the other cases of enlargement of the spleen and glands with changes in the bone-marrow, and blood containing large numbers of myelocytes, lymphocytes, and polymorpho-nuclear leucocytes;

but it is on the whole convenient to consider these groups separately. The spleno-medullary form is very much more frequent, and will be first described.

1. Spleno-medullary Leucocythæmia.

ÆTIOLOGY.—This variety is more common in men than in women. It may occur at any period of life, being most frequent between thirty and forty years of age. Deficient hygienic conditions, the disturbances of pregnancy, and the climacteric in women have been thought to have some influence. Gowers found that in women it was most frequent between forty and fifty; and that some cases began during pregnancy, and others soon after it. Malarial fever has been an antecedent in many cases; but a causal connection is uncertain. Race, heredity, and social position have no marked relation to the occurrence of the disease.

ANATOMICAL CHARACTERS.—*Blood.*—The blood is paler than normal, and may be greyish-red in colour. In extreme cases coagulation is imperfect; a grumous chocolate-brown mass results. After defibrination three layers form:—red corpuscles, white corpuscles, and serum. Under the microscope the white corpuscles are seen to be in great excess; instead of two or three in the field, there may be several hundreds. Enumeration (*p. 150*) shows that not only are the leucocytes increased, but the red corpuscles are diminished to such an extent that the total number of corpuscles is less than the normal. Instead of 5,000,000 per cubic millimetre there may be only 2,500,000, or even 1,000,000. On the other hand the leucocytes may be increased from the normal (7,000 to 10,000) to 600,000 per cubic millimetre, though the number very rarely rises over 300,000, and may be less. The proportion of the white to the red corpuscles may be 1:20, 1:10, or possibly 1:1; but the higher proportions are always largely due to the marked diminution of the red corpuscles, as well as to the increase of the leucocytes. In recording observations, the number per cubic millimetre of both red cells and leucocytes should always be stated (*p. 151*).

The further examination and enumeration of the leucocytes must be made with the help of blood-films (*p. 153*). The following changes are then observed (*see Coloured Plate, p. 156*). Of the leucocytes present (1) from thirty to fifty per cent. are so-called *myelocytes*, large cells, possessing a single large nucleus staining faintly, and fine oxyphile granules in the protoplasm. These cells are not found in normal blood, but are present in normal bone-marrow. (2) The *polymorpho-nuclear finely granular oxyphile cells*, forming the bulk of the leucocytes (70–80 per cent.) in normal blood, are enormously increased in number, although owing to the presence of the other varieties they may now only form 50 per cent. (3) *Eosinophile cells* are increased very nearly in proportion to the general increase of the leucocytes—that is, while they are more numerous, their percentage is not very different from what it is in health. Some of the coarsely granular eosinophile cells resemble in the shape of their nucleus the characters of myelocytes. (4) Sometimes cells whose coarse granules stain with basic dyes are seen (*mast-cells*). (5) The *lymphocytes* are relatively diminished from the 15 or 20 per cent. of normal blood to 7 or even 3 per cent. The red corpuscles may present slight differences in size and in shape (*poikilocytosis*). In addition, there are nearly always *nucleated red*

corpuscles (normoblasts) in considerable number. The fall in hæmoglobin is greater than the fall in red corpuscles, so that the colour-index (p. 152) of each red corpuscle is less than normal. The specific gravity of the blood is reduced from 1055, the mean in health, to an average of 1042, the change being due to an increased proportion of water, from 790 parts per 1000 in health to 840 in leucocythæmia. The fat and fibrin are increased as the iron is diminished. An interesting fact is the great increase of the xanthin-bases, which are believed to result from the destruction of the leucocytes. Lactic, formic, and succinic acids have also been found, and the alkalinity of the blood is slightly reduced. The octahedral Charcot-Leyden crystals have been found in the blood, and in many organs after death. They are not peculiar to this disease. See CHARCOT-LEYDEN CRYSTALS, p. 272.

Organs.—The *spleen* is always enlarged. Instead of the normal 6 to 10 ounces, it generally weighs 5 or 6 pounds; sometimes it is as little as 1 pound; and in one case it reached 18 pounds. It is uniformly enlarged, and maintains its normal shape. The capsule is thickened in places, and the organ is more or less adherent to the abdominal wall, diaphragm, or adjacent viscera. On section it often has a brownish rather than a red colour, and is homogeneous or marked with paler lines, due to thickened trabeculae. It is smooth, hard, and dry. Not infrequently there are large conical infarcts, triangular on section, yellow in colour or caseous if old, red if recent. The change in the spleen is one of great increase of the splenic pulp and of the trabecular tissue, the pulp being densely packed with leucocytes of the same kind as those found in the blood; the Malpighian corpuscles are usually inconspicuous.

The *bone-marrow* is either soft and yellow, like pus, or more commonly firm and pink. In either case, the fat of the normal adult marrow is replaced by a cellular substance, in which are found myelocytes, nucleated red corpuscles of various sizes, cells containing degenerating red cells, and giant-cells. These changes may be found in all the bones. It is most marked in those which possess most spongy tissue, as the ribs and vertebrae, but also occurs in the long bones. The compact tissue may be thinned and the bones enlarged or perforated (Mosler) in consequence. The lymphatic glands are not commonly enlarged in the spleno-medullary form; and, if enlargement does occur, only small groups of glands are involved. In such cases the periphery of the glands may present leucocytes similar to those found in the blood, and differing from the lymphocytes in the centre of the gland.

The *liver* may attain a weight of 5 or 6 pounds. It is uniformly enlarged, pale and smooth, presenting no obvious change in structure to the naked eye; though on close examination it is seen that the portal tracts are wider than normal, and the microscope shows that they are infiltrated with leucocytes, while the capillaries of the organ throughout are distended by similar cells. Fatty degeneration and atrophy of the liver-cells are also common. Hemorrhage may occur under the capsule of the organ.

The *kidneys* present very similar changes, slight if any enlargement, moderate pallor, more or less infiltration with leucocytes, and occasionally hemorrhage under the capsule, under the pelvic mucous membrane, or into the tubules or glomeruli. The renal epithelium may be granular or fatty.

In the *heart* there is often fatty degeneration of the muscular fibres, and both endocarditis and pericarditis may be among the terminal events of the disease.

Similarly the *lungs* may present the changes of bronchitis or oedema; and the pleural cavities frequently contain dropsical or inflammatory exudation.

In the *brain* hæmorrhages constitute the most frequent change, and are sometimes of sufficient size to be the immediate cause of death. Rarely diffuse sclerotic changes and scattered areas of acute inflammation have been found in the brain and spinal cord. Hæmorrhages are also found in the *retina*, in the *ear*, and under the *skin*. The former can be seen during life by the ophthalmoscope, and are accompanied by white spots and streaks, due to accumulation of leucocytes in the tissues and along the lines of the vessels, as well as by a marked enlargement and tortuosity of the retinal veins. The condition has been described as *leucocythæmic retinitis*.

SYMPTOMS.—The onset of spleno-medullary leucocythæmia is often very insidious. The patient suffers quite unaccountably from languor, weakness, loss of flesh, and perhaps shortness of breath. This may go on for some months, until at last the increased size of the abdomen leads to an examination, at which is revealed an enlarged spleen, already perhaps occupying half the abdomen. The early symptoms may include some sense of distension or pain in the splenic region, slight swelling of the feet, and even decided pallor; but it is very important to observe that the face often retains a good colour—that is, there is no obvious anaemia for a long time after the spleen is greatly enlarged, even when the blood presents in a marked degree the characteristic changes. In many recorded cases the early stages of the changes in the blood and spleen have not been observed. When discovered the spleen is thus often of large size, reaching three or more inches below the umbilicus, and within two inches of the middle line. It is distinguished by its sharp edge and one or two pronounced notches. When larger it may extend below to Poupart's ligament, and even into the pelvis so as to be perceptible by vaginal examination (Spencer Wells); in front it may reach and cross the middle line, the lower end extending for three or four inches obliquely beyond the umbilicus. This curved position of the organ is determined by its vascular attachment to the coeliac axis. The surface is smooth, firm, and sometimes slightly tender. Occasionally a peritoneal rub is felt or heard over it, and rarely a vascular murmur may be detected with the stethoscope. The presence of the enlarged spleen causes considerable enlargement of the abdomen, and often some pressure on the thoracic viscera. In an earlier stage or in a less marked case the spleen may only reach a few inches below the left costal margin. The edge of the liver is often two or three inches below the right costal margin; it is smooth, and moderately firm. The condition of the medulla of the bones is often not manifest during life; sometimes the sternum or the shaft of a long bone is tender to pressure or percussion.

The temperature is often, but not always, raised; and periods of considerable pyrexia may alternate with others in which there is little fever. The cases in which there is most pyrexia are usually the

most rapid. The pulse if little affected in early stages becomes rapid later. The patient may remain for several months, or even a year or two, with but little change, only slowly becoming weaker, paler, and thinner, with increasing size of the abdomen. But eventually, and in a few cases much more rapidly than is above indicated, serious circulatory difficulties supervene. The heart's action becomes enfeebled, the pulse is rapid and weak, palpitation occurs, the impulse may be displaced, and a systolic murmur is heard at the pulmonary cartilage, or even at the heart's apex. Dropsical effusions are common, the feet become edematous, and ascites or pleural effusion is recognised. Epistaxis often occurs comparatively early, but other hæmorrhages take place towards the end, from the bowels, stomach, lungs, or uterus, and into the joints and the connective and subcutaneous tissues. As already stated, they are found *post mortem* in many of the viscera. The hæmorrhagic tendency is such that injuries may give rise to serious loss of blood; the extraction of a tooth or a puncture for paracentesis has led to death; and excision of the spleen has more than once proved quickly fatal from this cause. In addition to the dyspnoea, which results partly from the anæmia, partly from the enfeeblement of the heart, and partly from the great size of the abdominal viscera, the patient may be short of breath from the occurrence of bronchitis, of œdema of the lungs, or of pleural effusion. For like reasons cough is of frequent occurrence. The functions of the stomach are interfered with by pressure, and indigestion and vomiting occur, as well as diarrhoea, which may be accompanied by hæmorrhage. The urine is acid, of high specific gravity; the urea is not much altered in amount, but there is an increase of uric acid and of the xanthin-bases. Albumen is not commonly present, except towards the end of the disease. In women menstruation is often arrested, but menorrhagia or metrorrhagia may occur. In men persistent priapism has sometimes been observed. The ophthalmoscopic appearances of the fundus of the eye have already been described; if the region of the yellow spot is involved vision will be affected. Similarly deafness has sometimes resulted from hæmorrhage into the structures of the ear.

The *nervous system* is not often much affected beyond the production of languor, weakness, and perhaps mental depression. Delirium and coma are occasional terminal events, and more rarely apoplexy, paralysis of the facial or other cranial nerve, or sudden deafness, results from the hæmorrhage or leucocytic accumulations already described.

DURATION.—Cases of spleno-medullary leucocythæmia have a duration of from about six months to seven years, the average of sixty-three cases collected by Gowers being two years; but the difficulty of knowing the date of the actual commencement must be remembered.

CAUSE OF DEATH.—The immediate causes of death in leucocythæmia are loss of blood from the nose or bowels, pneumonia, pleurisy, œdema of the lungs, cerebral hæmorrhage, cardiac dilatation and exhaustion.

PATHOLOGY.—The pathology of leucocythæmia is still obscure. It is certain that it is not primarily and solely a disease of the spleen. There are good reasons for believing (Muir) that the myelocytes give origin by division to the polymorpho-nuclear

granular leucocytes; and the unusual occurrence of the former in the blood, and the increase of the latter, point to an undue proliferation and growth of the marrow-cells, that is, to a disease of the marrow, as the primary cause of spleno-medullary leucocythæmia. The difficulty in this case is undoubtedly to account for the enormous size of the spleen. It may be due to the accumulation of leucocytes in great numbers, partly for the purpose of their destruction in the spleen; and to consequent tissue-change of a hypertrophic kind, such as thickening of trabeculæ and vascular development. But the relations between the size of the spleen and the amount of leucocythæmia, especially in the early stages, have to be explained. It may be that, where the spleen is enlarged with a slight degree of leucæmia, the spleen is accommodating most of the leucocytes that are poured into the blood; and that, as the spleen becomes more and more overloaded, the corpuscles must accumulate in the blood-stream.

There is absolutely nothing in the ætiological factors which helps to explain the lesion of the bone-marrow. The relations of ague to the spleen might be such that the spleen after ague was less active as a destroyer of leucocytes; but that would not account for the primary activity of the cells of the bone-marrow.

The relation of the disease to *microbes* is of course of the greatest interest, but remains unsettled. Fernie, Kelsch, and Vaillard found short rods, and others have found streptococci, and staphylococci. Löwit more recently has discovered in the corpuscles organisms of the nature of a sporozoon, to which he has given the name of *Hæmaphysa leucæmiæ magna*. He always finds it in the peripheral vessels in the medullary form of leucæmia, while in the lymphatic form he finds another parasite of a similar character. These observations appear to want confirmation, and strong doubts have been thrown upon them by Hirschfeld, Tobias, and Bloch.

DIAGNOSIS.—The diagnosis of spleno-medullary leucocythæmia rests on the enlargement of the spleen, and on excess in the blood of granular leucocytes and myelocytes. In all cases of splenic enlargement the blood must be carefully examined (p. 149), otherwise cases of *splenic anæmia* may be mistaken for leucocythæmia. If the leucocytes are in considerable excess, a fact which may be ascertained by simply examining a drop of blood under a high power, splenic anæmia is highly improbable; but the true test of spleno-medullary leucocythæmia is not so much the number of leucocytes as the existence of *myelocytes*, and the increased quantity of polymorpho-nuclear and eosinophile cells. Myelocytes may be present in early stages when the number of leucocytes is no greater than in an ordinary leucocytosis (p. 156). The special character of the leucocytes assists in the diagnosis of this form of the disease from the lymphatic variety, in which the lymphocytes form nearly the whole of the leucocytic increase.

It must be definitely made out that the tumour is the spleen. It is remarkable that an enlarged spleen in women has often been mistaken for an *ovarian tumour*. An ovarian tumour large enough to reach the costal margin is central in position, while the history will generally show that it began at the lower part of the abdomen. It is also important to bear in mind that leucocythæmia does

not at all stages produce marked pallor of the face; the patient may have a good colour when the spleen is large, and leucocyt hæmia pronounced.

PROGNOSIS.—The prognosis of this disease is bad. Improvement not infrequently takes place under treatment; the spleen may diminish remarkably in size, and the leucocytes may fall in number nearly to the normal. Similar changes even take place spontaneously, but they are generally temporary, and in every case a relapse follows and eventually death ensues. It is difficult in an early stage to estimate the future duration of the illness. Neither age, sex, nor apparent causation affords any help. The size of the spleen affords little information; but some idea may be gained by a consideration of the extent to which the leucocytes are increased, and the red corpuscles are diminished; the greater deviation from the normal being the more serious. Hæmorrhages are of grave augury, but epistaxis less than other forms. Cardiac dilatation, œdema, and albuminuria indicate an advanced condition.

TREATMENT.—Many drugs have been tried in this disease, but arsenic is the only one which has proved serviceable in any large number of cases. Under its use in some cases, the spleen has diminished in size, and the number of the leucocytes has fallen to nearly normal; but the benefit is rarely more than temporary. The drug may be given in increasing doses, up to 30, 60, or even 90 minims of the liquor arsenicalis daily. Iron, quinine, iodides, bromides, and mercury are practically useless. Mosler advised injection of Fowler's solution into the spleen; provided that the organ be firm, dense, and close to the abdominal wall, that there be no hæmorrhage manifested, and no high degree of cachexia. Temporary improvement has also been obtained by the inhalation of oxygen to the extent of 30 or more litres daily (Kimberger); and under this treatment combined with the administration of arsenic, remarkable improvement took place in a case under the writer's care; but it has not always succeeded. Excision of the spleen has been attempted, and has been invariably fatal—in most cases from uncontrollable hæmorrhage. Further trial of it does not, at present, seem justifiable; and if it is not the primary seat of the disease there is little reason for the operation. Similarly, though quinine, cold affusion, ergotin, and voltaic electricity may be employed to reduce the size of the spleen, whether it be a post-malarial condition, or a part of anæmia, or leucæmia, the course of the disease is little likely to be affected thereby.

In all cases one may make the attempt to postpone the inevitable end by reasonable care of the patient, by avoidance of physical and mental strain, by judicious diet, by maintaining a normal action of the bowels, and by protection from cold. Special symptoms may require treatment. Hæmorrhage must be checked by the usual methods, and solid perchloride of iron may be applied to accessible places. For splenic pain, counter-irritation, sedative liniments, and hypodermic injection of morphia may be used. For œdema or other indications of cardiac weakness, digitalis or liquor strychninae hydrochloratis may be employed.

II. Lymphatic Leucocyt hæmia.—The *ætiology* of this form of the disease is even less obvious than that of the spleno-medullary form. The cases are more rare, and present so many differences among themselves that classification is difficult.

Recently attention has been drawn (Fraenkel) to a group of very acute cases which appear to present distinctive features. As antecedent conditions he mentions anæmia, pregnancy, injury, and certain infectious diseases, especially influenza. The ages of his patients were from 13 to 34; but one of five cases recorded by Rose Bradford was 58 years old and another 7 years.

ANATOMICAL CHARACTERS.—The blood in the lymphatic forms is characterised by the predominance of those so-called uninucleated cells, with a non-granular protoplasm, which have gone by the name of lymphocytes, and have hence secured for this condition the name of lymphæmia, or lymphocyt hæmia. Ehrlich distinguished two kinds of these cells: one a small cell, not larger than a red corpuscle, with a large nucleus and a very small amount of protoplasm (lymphocyte); the other two or three times as large as a red cell, with a single nucleus and a large amount of surrounding protoplasm (large uninuclear). In several of the acute cases, it is the latter cells which have formed the bulk of the leucocytes. Hayem and Lion place no reliance upon the size of these corpuscles as a means of distinction, but divide them into those which are of small size, opaque, and staining deeply with reagents; and those which are translucent, stain feebly, and vary from the size of a red corpuscle to two or three times larger. The former only are the true lymphocytes; and, as they record cases of leucæmia in which the latter are predominant, the justice of the term 'lymphocyt hæmia' is by them held to be doubtful. In any case we have here cells which have an undivided round or oval nucleus, and do not contain granules. The diseased blood further contains usually some polymorpho-nuclear cells (2 to 5 per cent. of the total leucocytes), a very few eosinophiles, and occasionally a few myelocytes. The red corpuscles are deficient, falling often to 3,000,000, or less; nucleated red cells are rare. *Post mortem*, the blood may be of a brown, café-au-lait colour. The glands over the whole of the body may be enlarged, and present conditions not essentially different from those described under Lymphadenoma. The retroperitoneal, mesenteric, and intrathoracic glands are affected as much as those readily accessible during life. The glands are generally separate from one another, but sometimes matted together. They are rather soft, and whitish or pink in colour on section; they may present hæmorrhage in their substance. The spleen is moderately enlarged, but rarely reaches the size that is common in the spleno-medullary form; the liver is also enlarged. The medulla of the bones presents often the lymphoid transformation already described. The thymus is occasionally enlarged, and found persistent even in adults. The tonsils, the lymphoid follicles of the pharynx, and the solitary glands of the stomach and intestine are enlarged; or a more diffuse infiltration may occur as in the gums, which may ulcerate—so-called 'leucocyt hæmic stomatitis.' In addition there may be new-growths of lymphadenoid structure in various parts of the body (*see* LYMPHADENOMA), and, microscopically, all the infiltrated organs contain leucocytes of the uninucleated form; it is especially to be noted that in the affected bone-marrow these lymphoid corpuscles predominate.

SYMPTOMS.—The chronic form of the disease presents a general resemblance, so far as the

symptoms are concerned, to spleno-medullary leucocythæmia. The symptoms arise somewhat insidiously: the lymphatic glands enlarge in different parts of the body, the spleen and the liver undergo moderate enlargement, the patient becomes anæmic, and suffers from attacks of fever; and in course of time occur complications of hæmorrhage, albuminuria, passive effusions, and cardiac failure, similar to those seen in the other variety.

In the acute cases, to which reference has already been made, the duration is from 20 days to 8 or 9 weeks, or rarely as long as 16 weeks. The disease begins insidiously with general weakness and malaise, or it may be with some pains in the spleen and joints. The external lymphatic glands may then become enlarged, but they are not always very prominent. There is a slight or moderate enlargement of the spleen and of the liver, and the bones are sometimes tender. A prominent feature in many of the cases has been a severe form of stomatitis with sloughing and gangrene of the gums, but (in Rose Bradford's cases at least) without any implication of the subjacent periosteum or bone. With all this there is febrile reaction, a high degree of anæmia, and hæmorrhages from the gums, under the skin, and from the alimentary canal in the form of mælena.

PATHOLOGY.—The pathology is still under discussion. The association of enlargement of the lymphatic glands and of the other blood-forming organs with the new-growth of adenoid tissue throughout the body and with the condition of the blood suggests a process analogous to that of new-growth in all the lymphatic structures, in contrast with the spleno-medullary form in which the bone-marrow is thought to be primarily at fault. But this view has to be harmonised with our knowledge of Hodgkin's disease or lymphadenoma, in which there is growth of all the lymphatic structures without leuchæmia. Conversely a case is reported (Pappenheim) of lymphatic leuchæmia, or at any rate, of lymphocythæmia, without any swelling of the lymph-glands; here the bone-marrow was affected, and Pappenheim is led to the suggestion that even in the lymphatic forms the bone-marrow may be the primary seat of the disease.

Löwit's discovery of another organism, *Hæmaphysa leuchæmie vivax*, in the blood-forming organs has not yet been confirmed.

Fraenkel thought from the inflammation and sloughing of the gums that infection probably took place through the mouth, but in Rose Bradford's cases the gums appeared to be affected late in the illness.

DIAGNOSIS.—As in the other form the diagnosis can always be determined by a careful examination of the blood with an enumeration of the corpuscles. The blood should be examined in all cases presenting numerous glandular enlargements, and in acute cases, otherwise unexplained, beginning with stomatitis, gingivitis, and cutaneous hæmorrhages.

PROGNOSIS.—This is uniformly bad.

TREATMENT.—This can only be conducted on the same lines as above mentioned for the spleno-medullary form.

FREDERICK TAYLOR.

LEUCOCYTOSIS (λευκός, white; and κύτος, a cell).—A condition of the blood, in which certain of the white corpuscles are moderately increased in number. See BLOOD, Morbid Conditions of.

LEUCODERMIA (λευκός, white; and δέρμα, the skin).—White or achromatous integument. See PIGMENTARY DISEASES OF THE SKIN; and LEUCOPATHIA.

LEUCOMA (λευκός, white).—A white opacity of the cornea, generally the result of inflammation or ulceration of that structure. See EYE, AND ITS APPENDAGES.

LEUCOMAINES (λευκάμα, whiteness).—A term applied to a class of alkaloids resulting from the normal metabolism of the animal proteid tissues without the intervention of any bacterial agency. To the class of alkaloids resulting from the putrefaction of tissue the term *ptomaines* is given. See PTOMAINES.

LEUCOPATHIA (λευκός, white; and πάθος, a disease).—SYNON.: Albinism, Achroma, Leucoderma, Leucasmus. See ALBINISM; and PIGMENTARY SKIN-DISEASES.

LEUCOPLAKIA.—See TONGUE, Diseases of.

LEUCORRHŒA (λευκός, white; and ῥέω, I flow).—SYNON.: Fr. *Leucorrhée*; Ger. *Weisser Fluss*; Lat. *Fluor Albus*; Pop. 'The Whites'; 'White Discharge.'

DEFINITION.—A non-hæmorrhagic discharge, of pale colour, escaping from the female genital fissure.

ÆTIOLOGY.—Leucorrhœa is a symptom rather than a distinct disease; and may result from any of the morbid processes that lead to hypersecretion from the genital mucous surfaces, or from the glands opening upon them, whether the mucous membranes be injured or entire. It is, however, a source of much discomfort and deterioration of health, and so demands special treatment.

SYMPTOMS.—Leucorrhœa presents several distinct varieties according to the seat of its cause; and the symptoms of each variety require separate consideration.

1. **Vulvar Leucorrhœa.**—In this variety a glairy viscid secretion is found bathing the apposed surfaces of the pudenda, stiffening into a crust on the surface of the labia majora or on the insides of the thighs, and sometimes glueing the lips more or less firmly together at their margins. It is usually derived from the muciparous glands covering the internal surfaces of the labia majora and the nymphæ; but in cases of special eruptions and general vulvitis it may come from the vestibular surface; and in still rarer cases it is poured out from the glands of Bartholin. Vulvar leucorrhœa is met with at any period of life, but is most common in the young, *infantile leucorrhœa* almost always being of this variety. In cases of gonorrhœal infection in the female, the vulva is usually the seat of a profuse discharge which is apt to become purulent, but it is rarely confined to this situation, spreading both into the urethra, and upwards into the higher spheres of the genital mucosa.

2. **Vaginal Leucorrhœa.**—The discharge in cases of vaginal leucorrhœa is most frequently white in appearance, of acid reaction, and due to a secretion from the general surface of the vaginal mucous membrane. Its whiteness is found, on microscopical examination, to be owing to the presence of quantities of scaly epithelial cells, many of which are crowded with fatty particles, while others have been quite broken up in consequence of the fatty degene-

ration. Sometimes the discharge has a more yellowish tint, and then it is found to contain quantities of pus-cells among the epithelial scales. In the former group of cases we have to do with a simple catarrhal condition of the vaginal mucosa; in the latter there are red granulation-like spots scattered over the membrane, which has here lost its epithelial covering. Vaginal leucorrhœa is a complaint to which women are specially liable during the reproductive period. The catarrhal form is extremely common in young married females; while the other form occurs rather about the menopause, or, if occurring earlier, is complicated with some of the other varieties of leucorrhœa. Apart from specific causes, it may be brought on by sexual excesses; by the presence of a foreign body, such as a pessary; by a displaced uterus; by a chill; or by any condition that interferes with the circulation in the pelvis. In a large proportion of cases it is secondary to the next variety of leucorrhœa.

3. **Cervical Leucorrhœa.**—The discharge that comes from the canal of the cervix uteri is transparent, like unboiled white of egg, very tenacious, and of alkaline reaction. It may still present these characters as it escapes from the pudenda; but it generally becomes somewhat clouded as it passes through the vaginal canal, and gets acted upon by the acid secretion from the vaginal walls. Independently of this change in the vagina, it is sometimes found already more or less opaque as it lies within the cervical canal, and may be seen of a yellowish or greenish or reddish tint in various cases. The clear cervical leucorrhœa is seen under the microscope to be made up of a viscid magma, having entangled in it large numbers of columnar epithelial cells, which have a tendency to arrange themselves in rows. These are easily seen to be the ciliated epithelial cells that cover the normal mucous membrane, but deprived for the most part of their cilia. They are accompanied by smaller rounded cells like mucous corpuscles or wandering cells, partly derived from the interior of the crypts, and partly shed from the general surface from which the epithelium has been removed. In almost all cases some of the epithelial cells and mucous corpuscles are charged with fatty particles, and surrounded with granules, resulting from the breaking down of some of their number. The more turbid fluid, the more the cells are found to have undergone such degeneration; and where the discharge is profuse, fluid, and of yellowish colour, it has more the characters of a purulent fluid in which the relatively few cylindrical cells are changed in form, becoming oval or rounded, and nearly all reduced to a compound granular mass. The more deeply tinted discharges owe their discolouration to the admixture of blood, the red corpuscles of which can easily be recognised. Apart from the leucorrhœas of specific origin, this is the commonest of all the varieties. It may be found in females of any age, but specially affects women during the reproductive period, and more especially those who have been mothers. We can understand the special liability of the cervix to catarrhal affections, when we remember that all intra-uterine discharges pass through and may irritate it; that it is exposed to damage during the transit of the fœtus in parturition; that vaginal affections easily pass into it by continuity of structure; and that it may readily be injured by foreign bodies in the vaginal canal, or even by fretting of its orifice against the vaginal wall in

cases of displacement or excessive mobility. It is, besides, a favourite site for the lodgement of gonococci in cases of 'latent gonorrhœa.'

4. **Intra-uterine Leucorrhœa.**—Here also the discharge is transparent, like white of egg, and alkaline in its reaction, but it is more fluid than the secretion from the cervical canal, and may escape as a clear liquid from the genital fissure. In cases of long standing, more particularly where there exists some organic disease in the uterine parietes, the fluid becomes turbid, purulent, and more frequently than in any other variety of leucorrhœa tinged with blood, even alternating with irregular discharges of blood. Under the microscope we see many cylindrical epithelial cells, not infrequently ciliated, along with groups of smaller cells, partly cylindrical, partly rounded, that have been discharged from the uterine follicles, all embedded in a mucous fluid. Where the discharge is more turbid, the epithelial cells are seen to be undergoing fatty degeneration, and to be accompanied by wandering cells, pus-globules, and crowds of free fatty particles. This uterine leucorrhœa may be found at any period of life, but as an independent affection it is found almost exclusively in virgins or young married women, or in women who are ceasing, or have ceased, to menstruate. In the last-named class of cases the cervix is often atrophied, and its orifices narrowed; and the intra-uterine secretion may accumulate for a time, and be expelled with some degree of suffering, and having a fœtor that may raise a suspicion of cancer. Most frequently it is found associated with cervical leucorrhœa, the endo-cervical affection having passed up to the endometrium, or, more rarely, *vice versa*. Perhaps the most frequent form of it is found in women who are subject to a leucorrhœal discharge before or after the menstrual periods; and in the cases of amenorrhœa where a pale discharge escapes at the usual menstrual periods, this has its source in the interior of the uterus proper.

5. **Tubal Leucorrhœa.**—Doubtless some small portion of the fluid that escapes in certain cases of leucorrhœa is furnished by the Fallopian tubes; but despite the elaborate attempts of Hennig and others to establish a distinction between it and the other varieties, it remains rather as a subject of pathological interest than of clinical importance, and need not occupy us further here.

DIAGNOSIS.—The statements of a patient in regard to a leucorrhœal discharge cannot be relied on in establishing a diagnosis as to its source. If it be white and flaky we may judge that it is vaginal; if more transparent, and escaping in half-coagulated flocculi, we may conclude that it is cervical; while a clear and more continuous and fluid discharge would be more justly referred to the uterus proper. But it is never safe to trust merely to the appearance of the discharge as it escapes from the vulva, for it may have become modified as it lay in or traversed some part of the canal, or may be compounded of fluids derived from different surfaces. The seat of the discharge must therefore be exposed. In the vulvar variety it suffices to separate the labia and occasionally to expose the navicular fossa and the orifices of the Bartholinian ducts, by passing the finger into the anus. The vaginal form of leucorrhœa requires for its detection the use of a speculum, duck-bill or tubular; and the cervical, one of these or a bivalve speculum. For the diagnosis of intra-uterine leucorrhœa it is sometimes helpful to remove

some of the fluid for microscopical examination by means of a fine syringe. Unless a clear history of infection can be obtained, or the presence of gonococci verified by the microscope and culture, it is almost impossible to establish a distinction between a gonorrhœal discharge and the simpler catarrhal leucorrhœa. In the former there is a very notable tendency to spread through all the contiguous mucous surfaces; and while the vulva is likely to be predominantly affected in acute attacks, in chronic cases the germs lodge more frequently in the cervix or in the Fallopian tubes.

TREATMENT.—In instituting our treatment of leucorrhœa it is of the first importance to have in view the *constitutional* condition of the patient; to use means to counteract any diathetic tendency—tubercular, strumous, or syphilitic; and to raise as far as possible the general standard of the patient's health, by the administration of tonics and the enforcement of a suitable diet and regimen. It is partly in this way that a change of residence is often useful; and in making a change, it is well for the patient to go to some of the spas, such as Ems or Kissingen, the waters of which are helpful in reducing congestions and catarrhs of the pelvic viscera. In young women of relaxed habit of body, it may be enough to prescribe quinine and iron or arsenic, and the daily use of a cold sponge bath; and in infantile leucorrhœa, cod-liver oil and iron should be administered.

In the great majority of cases of leucorrhœa some kind of *local* treatment becomes an absolute necessity. Sometimes it is enough to pay strict attention to cleanliness, washing the pudendal surfaces with a soft sponge, or syringing the vaginal canal with tepid water; and even when astringent applications are to be made, the surfaces should first be subjected to a detergent stream of water. Where there is marked congestion of the uterus it is best to make the injections with hot water, and to keep the stream passing through the vagina for at least five minutes at a time; the immediate relaxation of the blood-vessels and hyperemia being followed by contraction of their walls, which favours the cessation of the discharge. The astringents most serviceable for checking *vulvar* and *vaginal* leucorrhœas are alum, aluminated iron, acetate of lead, sulphate of copper, sulphate of zinc, borax, and infusions of oak-bark, matico, and other vegetables charged with tannin. They are best applied in the form of an injection with a Higginson's syringe, having a vaginal nozzle attached to it; or of a douche through a long india-rubber tube, with a stop-cock, for regulating the flow, fitted close to a glass vaginal nozzle, and the other extremity opening into a wide receptacle, or fitted to a filter or pitcher into which the fluid is poured. Where there is a difficulty in using the injection, and where it is desirable to keep up a more prolonged application of the medicament, it may be introduced into the vagina in the form of pessaries made with cacao-butter or with gelatine. Topical applications to the canal of the cervix and cavity of the uterus ought always to be made through the speculum, and without such applications it is a hopeless task to undertake the cure of *cervical* leucorrhœa. Here, more concentrated or more powerful astringents or escharotics become necessary. Nitrate of silver in the form of a stick of caustic is easily applied, but its repeated application will lead to mischief. Zinc-alum, dried sulphate of zinc, sulphate of copper, perchloride of iron, or

tannin may be introduced, in the form of rods or arrows made with starch and gum. If a uterine sound or stilette be dipped in water and a thin film of cotton wadding wrapped round the point to the length of about two inches, the adherent mucus can be cleared away, and the same or another sound mounted with wadding can be charged with fuming nitric acid, the acid nitrate of mercury, strong carbolic acid, a solution of perchloride of iron, tincture of iodine, or iodised phenol, and carried through the speculum along the cervical canal. In *intra-uterine* leucorrhœa it becomes necessary to carry the application right up in the same way to the interior of the uterus. It is usually best to begin with one of the stronger liquids, apply it a few days after a menstrual period, and follow it up with applications of iodine. So long as the stilette or sound with the dry wadding passes easily through the os internum, it is usually necessary to continue from time to time the intra-uterine application.

LICE, Diseases due to.—See PEDICULUS.

LICHEN (λεῖχην—secondary signification—an eruption).—This term was used by the old writers to signify a large group of diseases usually distinguished by the appearance of a papular eruption. A more correct knowledge of their ætiology has, however, resulted in the reclassification of many of these diseases. Thus, Lichen urticatus is now relegated to the true urticarial group; while Lichen simplex and Lichen agrius are known to be stages in the development of eczematous and other diseases. There remains only the disease now usually termed Lichen planus. Two or three other conditions in common parlance still retain the name, and will be referred to later.

Lichen planus (SYNON.: *Lichen ruber*) is a disease characterised by an eruption of small papules, caused by the presence of infiltrating cells of inflammatory character in the upper layers of the cutis, with certain changes in the epidermis and neighbouring structures. The papules develop slowly, and the infiltrating cells show no tendency to rapid degeneration or to supuration. In consequence, the disease is usually of long duration, and is limited in distribution. Occasionally its course is acute, and the eruption universal. The papules when first seen are minute, slightly raised, sharply defined, and separate one from the other. As they increase in size (up to about 5 millimetres in diameter) their angular outline, just noticeable in the earlier stage, becomes more marked; thus, in the fully developed discrete papule, the shape is distinctly polygonal. The top of the papule as a rule becomes flat, and frequently shows a smooth polished surface, with a small depression corresponding to a hair-follicle or sweat-duct. When this is the case the mouth of the hair-follicle becomes filled with a plug of epithelium, which often projects as a conical peg from the surface of the papule. By this means the

papule of the disease occasionally has an acuminate shape, and in certain stages and certain cases the acuminate variety of papule is common. In course of time the epithelial plug in the follicle falls out, and a central depression is left, which is a very characteristic feature of the plane papule. These acuminate papules serve to emphasise the close relationship between lichen planus and the rare disease known as *Pityriasis rubra pilaris* (Devergie) in this country, and as *Lichen ruber acuminatus* by German observers.

The colour may be scarcely different from the surrounding skin, but usually the papules are a characteristic tint of purple or red, which varies with the acuteness of the process and the natural complexion of the patient. The eruption may appear on any part of the body, but is often especially marked on the flexor surfaces of the forearm and wrist, in the neighbourhood of the knee, and on the shin. Early and slight manifestations of the disease may be specially easily identified where the skin is fine and free of hair. The cutaneous papules tend to become capped with a fine scale of desquamating epithelium, and this feature of scalliness becomes more evident as the disease becomes chronic, and as the papules coalesce to form patches.

The eruption is frequently seen on the buccal mucous membrane, producing greyish-white points and streaks on the inner surface of the cheeks and lips, and leucoplakia of the tongue.

The subjective symptoms vary widely. The discomfort, if any, is generally slight; but sometimes the sensations of burning, itching, and tingling may be so severe as to threaten the life or mental condition of the sufferer.

The disease is rare before the age of twenty. Chronic lesions may be found in extreme old age. It seems to affect both sexes fairly equally. It is supposed to show a special preference for persons of the educated and leisured classes, and for those with neurotic tendencies.

The cause of lichen planus is uncertain. Some regard it as of toxæmic, others of nervous origin.

Three varieties may be recognised:—

1. *Acute lichen planus*.—The disease occasionally occurs as an acute eruption, appearing rapidly over the whole surface of the body. Along with the eruption of the characteristic papules there is a considerable amount of general erythema. The papules may coalesce to form small rounded patches or rings, but do not give rise to sheets or thickened patches of disease. The erythema soon disappears and the papules flatten out and are absorbed, leaving slightly pigmented spots, which in their turn also vanish. The whole course of such an attack may last for three or four months; local patches of the eruption, especially on the extremities, remaining for a little longer. This type of the disease appears to occur most commonly in young persons, and, in spite of the rapidity of appearance and large amount of the eruption, the discomfort may be very slight. The pruritus and irritation of the skin depend greatly on the general health and nervous condition of the patient.

2. *Chronic lichen planus*.—The majority of the cases run a more chronic course. Certain areas of the body are specially liable to become affected, such as the forearms, the thighs, the legs, the back, and abdomen, but usually, in addition, a number of papules are disseminated over the body,

though these may be so insignificant as readily to escape notice. In the areas specially selected by the eruption in any individual case the lesions tend to coalesce, and thus to give rise to patches of eruption sometimes reaching several inches in diameter. In such cases the purple or livid areas of the disease, slightly raised above the surface, traversed by the natural lines of 'skin-cleavage' exaggerated by the eruption, and covered by numerous fine greyish-white scales, are very characteristic. In other cases the eruption appears in ringed or circinate figures, while in others a distinctly linear distribution is observed. The lines of eruption are frequently the lines of pressure of garments, &c., or of injury to the skin by scratching.

3. *Lichen planus verrucosus*.—When the disease is markedly localised the coalescence of the chronic papules, the thickening of the cutis, and the increase of the horny epithelium give rise to the variety of the disease known as *hypertrophic lichen planus* or *lichen planus verrucosus*. This form is usually found on the extremities, especially on the legs. The peculiarly tinted dry, thickened, and scaly patches of eruption are easily recognisable. There may be observed in nearly every case outlying individual papules of the eruption presenting the characteristic flat-topped appearance; these serve to distinguish the disease in case of doubt.

The disease occasionally becomes widely *diffused*, and is then difficult to distinguish without critical examination from severe cases of general psoriasis, and shares with this disease the unfortunate liability to degenerate into one of the secondary forms of general exfoliative dermatitis. The disappearance of the eruption is followed by pigmentation, sometimes so dense as to give rise to a slate-brown or sepiæ discolouration of the affected part, even in cases in which no arsenic has been administered. The pigmentation gradually disappears, but may remain for years after the lesions have vanished; this is one of the most characteristic features of the disease. It is not very uncommon to find atrophic points and patches as the sequel of an eruption of lichen planus.

A form of disease probably allied to the diffuse form of lichen planus, showing areas of erythema differing in intensity with papular lesions, has been described under the title of *Lichen variegatus* (*Parakeratosis variegata*, Unna), and is under investigation at the present time.

HISTOLOGY.—The most noticeable lesion occurs in the cutis, and consists of dense collections of mesoblastic cells occupying chiefly the upper papillary layers. These cells are about the size of leucocytes, and consist of a single nucleus, with a small surrounding border of protoplasm. They degenerate and disappear slowly, and may possibly be converted into ordinary connective-tissue cells. Along with these cells are others resembling leucocytes, showing a tendency to fragmentation of nuclei and rapid disintegration of the cell. The cellular infiltration is densest in a group of papillæ immediately underlying the centre of the papule, and extends in gradually diminishing lines and streaks along the cutaneous vessels into the surrounding cutis. The lymph-spaces are widened, and there is a certain amount of dilatation of the blood-vessels with consequent œdema. The changes in the epithelium are not so marked, and consist chiefly of a tendency to overgrowth of the cells of the rete mucosum. The stratum granulosum is as

LICHEN

well defined or even thicker than normal, and in the chronic varieties the horny layers are also thicker, producing the hyperkeratosis so characteristic in lichen planus verrucosus. As a result of the thickening of the cutis, and the formation of a firm overlying horny layer of epithelium, the surface of the papule becomes flat, and develops the polished surface of the typical papules of lichen planus.

PROGNOSIS.—The prognosis of cases of lichen planus is nearly always good. In the acute cases recovery is often rapid, and in the course of a few weeks pigmentation only is left in the positions of lesions. In the chronic and localised variety on the other hand, especially of the verrucose type, the duration of circumscribed patches is indefinite.

TREATMENT.—*Local.*—The first indication is to allay local irritation. For this purpose anti-pruritic remedies, such as carbolic acid, resorcin, &c., as local applications are useful. The combination of mercury with anti-pruritics of this class is often advisable, as this drug appears to promote the absorption of the lesions. In acute forms of the disease the use of lotions of the glycerine of the subacetate of lead, 5 per cent. to 10 per cent., with 1 per cent. to 2 per cent. of added carbolic acid, are useful in the first stage of treatment. Later, when the disease becomes localised, the use of an ointment or paste containing the remedies indicated, either as an inunction or as a covering to the patches of disease, is of more value. For this purpose the following ointment may be used: Carbolic acid, 4 parts; perchloride of mercury, $\frac{3}{4}$ –1 part; zinc ointment, to 100 parts. If much scaliness is present the use of salicylic acid or resorcin is to be recommended. Other remedies of service are the liquor picis carbonis, oil of cade, oleum rusci, the salts of mercury such as ammoniated mercury, and sulphur. When the condition of lichen verrucosus is attained, more severe local measures must be used to remove the horny epithelium. For this purpose thorough washing of the patches with a lotion of soft soap and alcohol, or the application of strong ointments or plasters of salicylic acid, should be employed. After the removal of the epithelium, milder treatment by means of the remedies already mentioned may be adopted. In the most chronic and warty patches much benefit is obtained by light curetting or scarification, or even by gentle cauterisation of the patches.

Internal treatment is often necessary, and should in nearly all cases be of tonic character. Change of air and relief from wearing occupations are to be advised. Such persons benefit from the judicious use of specially prepared foods, digestive tonics, cod-liver oil, and iron. Phenazone and other allied remedies are of value in the treatment of patients suffering from nervous excitement and irritability of the skin. Two drugs have been much used on account of their supposed specific effect on the disease, namely, arsenic and mercury. Of these, arsenic is of little value. On the other hand, the judicious use of mercury in the form of small and frequent doses of the perchloride seems to have a distinct effect, both in the cure of acute cases, and in aiding the resolution of the chronic lesions.

Lichen Circumscriptus.—A name applied to a circinate and papular eruption occurring on the trunk. It is one of the forms assumed by seborrhoea corporis or dermatitis seborrhoica.

Lichen Pilaris.—The name applied to a papular eruption affecting the hair-follicles, especially

in children, the lesions of which are frequently grouped and surmounted by horny spines of considerable length. The term *L. spinulosus* is also applied to this condition. It is a rare disease, and should not be confused with the slightly inflammatory hyperkeratosis of hair-follicles common on the external surfaces of the arms and thighs, especially in those suffering from slight xeroderma, to which the name has occasionally been given, and which is also known as keratosis pilaris.

Lichen Urticatus.—A common eruption in childhood, and probably the result of urticaria.

JAMES GALLOWAY.

Lichen Scrofulosus.—**SYNON.** : Lichen Scrofulosorum.—The name lichen scrofulosus has been given to an eruption of somewhat infrequent occurrence, characterised by the evolution of numerous indolent miliary papules, due to a folliculitis of little intensity, disseminated or usually with a strong tendency to group in clusters, which may be arranged in crescents or circles. The eruption may be copious or scanty, and then easily escapes recognition. The favoured sites are the flanks and sides of the abdomen, but other parts of the trunk, and even the limbs, may be involved. The colour of the papules is reddish from the inflammatory congestion, but when the latter subsides a tawny hue results, or some temporary pigmentation or slight atrophy is left. Well-formed papules are more or less rounded or conical, but in involution become flat-topped. It should be noted also that, like other follicular papules, tiny spines may project; that occasionally the composite character of the patches may be obscured by a degree of scaling; and that some acneiform papules may be intermixed with the simple papules. The eruption is somewhat capricious, appearing suddenly, and sometimes disappearing rapidly when the patient is placed under favourable conditions. It is an affection for the most part of childhood.

The association of this eruption with tubercular lesions of various kinds is very striking. Histological research discloses an architecture which is extremely suggestive of tuberculosis, and the presence of tubercle-bacilli has been noted. A local reaction has been observed after tuberculin-injections, and there is some evidence that inoculation of the papules into animals may produce tuberculosis. Such evidence has rather displaced the old theory that the eruption was the outcome of some cachexia, which was suggested by the multitude of papules, the benignity of the eruption, the absence of any local infective progression, and the capricious behaviour of the eruption. There is still some difference of opinion as to whether the eruption is due to the presence *in loco* of tubercle-bacilli of feeble infective power or to the circulation of toxins in the blood from some tuberculous focus.

DIAGNOSIS.—This eruption has to be distinguished from the other minute papular eruptions developed in connection with the follicles, but the combination of symptoms set forth will generally serve to make the distinction. Three eruptions may be specially mentioned: (1) a rare affection of childhood—the Lichen spinulosus of Devergie—in which a few symmetrical clusters of follicular papules are localised on various points of predilection, such as the hips, shoulders, and back of the neck; (2) the disseminated follicular papules of 'eczema seborrhoicum'; and (3) the papular clus-

tered eruption of acquired syphilis, which is very rare in childhood.

TREATMENT.—This must be directed to the promotion of the general nutrition of the patient by such dietetic, hygienic, and medicinal or surgical measures as will serve to cure or remove any tuberculous foci and prevent infection. Cod-liver oil internally and as inunctions has been especially recommended.

T. COLCOTT FOX.

LIEBENSTEIN, in Saxe - Meiningen.—Chalybeate waters. See MINERAL WATERS.

LIENTERIC (λεῖος, smooth; and ἔντερος, the intestine).—A form of diarrhoea in which the stools contain much undigested food, in consequence of its having passed rapidly along the alimentary canal. See DIARRHŒA; and STOOLS.

LIFE-ASSURANCE.—The great extension of life-assurance of late years has placed the solution of important questions involving large financial operations within the range of the daily work of the medical practitioner. It is important, therefore, that his duties and the nature of the knowledge required of him should be defined. We shall dwell briefly on the nature of life-assurance, and point out the rules which should guide the medical adviser of a life-assurance office in forming an opinion. We shall then consider the principal agents which modify the duration of human life, and their bearing on the questions submitted to us. Life-assurance is a contract of indemnity. The amount of the indemnity to be paid on death is fixed by each individual according to his means or wishes, and the company engages to pay the sum when life fails or under other conditions, in consideration of an annual or other payment or premium so long as the contract lasts.

Irrespective altogether of health, the risk undertaken by the company is greater or less according to the variation in two factors: (1) the age of the life to be assured; (2) the duration of the term of assurance. The premium required for an assurance on a life aged forty is greater than that for a life aged twenty; and again the premium for an assurance over the years of life from forty to sixty is greater than that for an assurance from forty to fifty only. As the premium is calculated on the assumption that the proposer has a chance of surviving to the extreme limit of life, it is obvious that the company ought to insure at the ordinary rate of premium such lives only as have the best chance of attaining to old age, or, as they are called, *first-class lives*. Hence lives coming under any of the following classes must be discarded from the first-class standard:—

1. Lives not possessed of sufficient vital power to afford them the possibility of attaining old age. This will include persons who have shown a tendency to certain diseases which will develop later on in life, as gout, rheumatism, &c.

2. Lives whose family history discloses a tendency to early death.

3. Lives whose place of residence or occupation has a more than usual effect on life, or involves peculiar hazards.

Generally, lives which fall short of the highest standard in respect of one out of these three conditions may often be accepted, but if they fail of the highest level in more than one condition, they must be excluded. The ideal, therefore, which the medical examiner should set before himself as

constituting a first-class life, is the exclusion of these three conditions.

The tables of *expectation of life* put before medical examiners, which are deduced from the Institute of Actuaries' HM tables, and are based on the mortality of healthy males whose lives had been assured with twenty British life-offices, are often misunderstood. Expectation of life indicates the average number of years which is lived by all persons of a common age, from that age up to the extremity of life. The total number of years that will in the aggregate be lived by a group of persons of the same age, divided by the number in the group, gives the 'expectation.'

The medical examiner is for the time being the retained adviser of the office which employs him. Any medical man may decline to act for a company, but, if he has accepted a fee, he is bound to consider their interests as of primary importance, and his relations with his patient as secondary. He should not, therefore, allow himself to be swayed by motives of personal friendship, or because he is or has been the ordinary attendant of the proposer. Generally speaking, it is not judicious to employ the ordinary medical attendant of a proposer to report for an office, but it is often necessary to obtain his evidence confidentially, and, unless he decline to act, he is bound not to withhold any information he may have regarding the health, habits, or family history of the life. Every examiner should be aware that his report and opinion are necessarily submitted to the physician of the company, and thus a greater accuracy in the use of medical terms will often be observed.

The examiner will have an interview, always private, with the proposer, who should not be accompanied by any one. The wife may ask that her husband or friend shall be present, but this is not advisable. Persons of either sex are always more frank when alone with their doctor. There may indeed be ailments kept secret even from a wife or husband, or former events in life bearing on health, which would not be revealed in the presence of a third party. It is scarcely necessary to advise that the utmost courtesy and quietness of manner should be observed, and the proposer placed at his ease as much as possible. A deterrent inquisitive manner is apt to give rise to prevarications or concealment in the replies given.

An inquiry into the functions of the body is often resented when put abruptly, but the writer has never failed to obtain all necessary information by a quiet questioning. He is in favour, however, of direct questions, plainly spoken out, especially with women; but *many* questions of the kind are to be avoided.

Regarding temperance, it is generally useless to put the question directly to a proposer. His estimate of what constitutes excess may not be yours. His opinion of his own habits may be comparative as regards his neighbour, and he may be a dram-drinker (the worst form of excess) yet never 'get drunk'! It is well to approach the subject with inquiry as to his hours, habits, neighbourhood, and society, and thus elicit both his favourite drink, and how often it is taken.

The proposer being placed in a good light, the examiner will notice his general build, corpulence or otherwise. The face and hands will especially occupy him. The face may indicate intemperance, sensual habits, or nervous excitability. It should

be neither pale nor flushed, free from blotches, and the nose not unduly red. The drunkard's nose, protuberant, granulated, and rosy at the end, is often associated with a blear-eyed state of the eyelids. There are some forms of skin-affection which simulate it, but the practised eye will discriminate the chronic effects of alcohol which, by impairing the elasticity of the capillaries, has given rise to the nose here indicated. A flushed state of the mæ may lead us to suspect phthisis; while redness of the cheeks composed of permanently dilated blood-vessels, together with a velvety integument exuding sebaceous matters, always caused Brinton to suspect kidney-disease.

The hand affords evidence of various kinds, and its form, colour, and nails should always be regarded. We may thus detect gouty thickening; or, from the clubbed state of the fingers and incurved nails, be enabled to detect chronic phthisis, or old pleuritic or pericardial disease. The tongue should be examined, not only as regards its being furred, fissured, moist, or dry, but also for ulcers or growths, which, if present, should always be examined by pressure of the fingers. The throat may also give evidence of present or old syphilitic ulceration. The gums may present the blue line of lead-poisoning, or the dark-red line of phthisis. The gait, nervousness of manner, twitching of muscles, inability to walk straight, peculiarities of the eye-balls and facial muscles, or other symptoms, will betray some deep-seated affection of the nerve-centres, and the patellar reflex should be examined if any suspicions arise. Tremblings or shakiness of handwriting may indicate alcoholism, or abuse of tea or of smoking.

The teeth may be deficient or carious, and their condition is often a good test of general health. The notched teeth of syphilis should always be looked for. Finally, the whole aspect of a man should be noted, as conveying that he is robust, hearty, and vigorous, well developed in muscle of chest and limbs, or puny and weak, with loose tissues and flabby muscles.

The chief duties of the medical examiner are to ascertain with precision:—

(1) The *family history* of proposer; (2) his *past history*; (3) his *present state* of health; and (4) his *habits*.

1. The *family history* is to include not only his parents, brothers and sisters, and grandparents, but the health and ages at death both of them and their descendants collateral to proposer—that is, of uncles, aunts, and first-cousins. These facts need not all be recorded in the report paper supplied by the office, but their elucidation often enables the examiner to form an opinion as to the eligibility of a life where any taint, as consumption, gout, or cancer, exists in one generation. In case of deceased parents, brothers, and sisters, the exact causes of death should be given. If these are unknown it is important to state any facts concerning the symptoms and duration of the fatal illness which may enable an approximately accurate conclusion to be drawn.

2. The *past history* of a proposer will occupy us with much care. He is bound to tell us whether he has ever had any serious ailment; but, as memory is fallacious, the direct questions which are found in every form of medical report issued by the offices are to be put. It will be convenient then to ask in detail whether he has had symptoms of diseases

affecting the chest, head, and abdomen, or any disorder of a general kind, as fevers; and young men should be asked plainly about syphilis.

Inquiry should be made as to former residence in an unhealthy climate, or at any special place on account of defective health; also whether proposer has had any medical attendant, and, if so, for what.

3. The *present state* of health is then to be ascertained, and a careful examination made of chest and abdomen. We cannot insist too strongly on the necessity for *uncovering the chest*. Without this, percussion cannot be practised, the expansion, the movements, and alterations in the walls, caused by congenital malformation or by former disease, as pleurisy and phthisis, must escape notice. The heart-sounds cannot be estimated through the dress; and we have known many instances in which morbid conditions were overlooked because the proposer was so examined. There are heart-murmurs and lung-sounds which can be simulated or disguised by a well-starched shirt. For the examination of the *abdomen* the waistband should be unloosed, and palpation and percussion practised, by which the existence of enlargement of the liver or spleen, or of tumours, may be ascertained: for this purpose the reclining posture should be adopted.

4. By the *habits* of the proposer we understand his general mode of living, and his opportunities for exercise, but above all his temperance or excess in the use of stimulants. The average quantity of stimulants taken daily should be written down from the reply of proposer on the document which he has to sign. The testimony of friends is always asked on this point, but the replies are generally fallacious, and often consist in a 'Yes' or 'No' to the queries sent to them. In proposals important as to amount, a written statement as to the friends' estimate of the habits of a proposer should be obtained in the form of a letter, and not on a printed form.

5. *Age*.—Different ages predispose to particular diseases. Respiratory diseases prevail most from puberty to twenty-five, and this is the age when phthisis is most fatal. It has been reckoned that at forty half the danger from this disease is over, and three-fourths at fifty years of age; and the rule seems a fair one. An heredity to the development of phthisis at a somewhat advanced age—say after forty—may, however, exist, and prove an actual danger to life. The liability to certain diseases, as gout, apoplexy, degeneration of organs and blood-vessels, and also urinary affections, increases after forty, and it is at and after middle life that the temptation to excess in diet and stimulants, with a diminished desire for exercise, leads the way to slow organic alterations. Persons who attain to great age are generally spare, and have in almost all instances been frugal in their habits, and active in mind and body. The decay of muscle and of organs is precipitated by want of use, and the due exercise of all faculties of mind or body is conducive to longevity. It is good to compare the apparent with the actual age of a proposer. As a general rule, when he is really older than he looks, his expectation of life surpasses the average, and when he has aged beyond his years the risk is thereby so far increased.

6. *Occupations*.—The life which is protected from the vicissitudes of fortune by a fair provision for daily wants, which has occupation for both mind and body, without undue strain or the necessity for

hurry, and which has daily exercise in open air, combined with a moderate amount of sedentary work—is undoubtedly the best risk. The clergy are perhaps the best lives of all callings, and the statistics of the clerical offices bear out this statement. Teachers, heads of schools, lawyers, and physicians probably come next. The 'business' class, which includes merchants, stockbrokers, bankers, manufacturers, directors of companies, &c., is fairly healthy, and stands among the first on the list, but the examiner will do well to remember the anxieties incident to all these callings.

There are certain classes exposed to manifest dangers, for which special rates are demanded by all offices. Thus the publican is charged 1*l.* per cent. extra for occupation, a sum which appears to be scarcely sufficient.

7. *Heredity*.—Heredity plays an important part in the life-history of every individual, as there can be no doubt that physical, mental, and moral characteristics are often transmitted from ancestors. The whole constitution may not be so communicated; and parents may be mere transmitters along a chain, their offspring representing an earlier ancestor. The examiner will therefore inquire both about parents and grandparents. In tracing the effects of transmitted disease we should find how far others of the same generation, as brothers, sisters, and cousins, may have been affected by it. We have thus a gauge of the intensity of the transmission. Longevity, which implies the perfection of the whole animal system, is no doubt hereditary in some families. If both parents have been the subject of the same disease, the heredity is intensified in the offspring. A disposition to zymotic diseases is marked in certain families. The tendency to insanity is intensified by successive inheritance; that to syphilis is lost in the repetition of inheritance. Phthisis and cancer become intensified by inheritance, and appear earlier in each generation. Double inheritance (both parents) induces an earlier and a more rapid form of disease. Heredity appears to influence the sexes equally. *Forms* of disease run in families: in some the consumptive taint is shown in acute tuberculosis, in others the most chronic form of fibroid phthisis prevails. The *mother's* transmitting influence seems greater than the *father's*, and it is common to all hereditary diseases for the mother to transmit to sons and the father to daughters. *Family phthisis* appears at an earlier age as we descend the genealogical tree; thus, the grandfather may have it at sixty, his sons at forty, and his grandsons in early life.

Cancer is hereditary in one-third to one-seventh of the cases. It is most prevalent between forty and sixty. Encephaloid cancer is met with earlier; scirrhus cancer from forty to fifty; epithelial cancer later. The risks of hereditary cancer therefore increase with age after a certain point, while those from phthisis diminish. The rule must be to reject the issue of two cancerous parents. The heredity of *rheumatism* and *gout* is incontestable. Hereditary gout appears early, often at eighteen to twenty; acquired gout appears about forty. If both parents, or even one, have had several acute attacks of rheumatism, there is great likelihood of transmission to the child. *Diabetes* is allied to gout and rheumatism, and comes after the latter in frequency of heredity. *Heart-disease* claims the same heredity as gout and rheumatism; and while the acute form in the parent is apt to be repre-

sented in the child, it is not to be forgotten also that such parents commonly transmit a tendency to slow thickenings of the valves to their children, who may never suffer from the acute form. The many instances of valvular lesions met with in practice, where the individual has had no acute attacks, may often be thus accounted for. If one parent have had gout or rheumatism severely, the proposer being in perfect health, the heredity may be overlooked; but if both parents have had these affections the life should be declined, or a large addition made to the premium.

It has been found that *asthma* was hereditary in fourteen cases of thirty-five, and in seven it was paternal and direct. The most frequent period of development was in youth, and next in old age. If both parents were asthmatic, an addition should be made to the premium. *Albuminuria* may be regarded as only transmissible when the result of gout or alcoholism in the parent.

Intemperance must be considered as hereditary in a high degree. It runs in families, who not only inherit the nervous constitution which drunken parents transmit, but that peculiar temperament which flies to stimulants as a resource on any emergency of life. The *craving* for drink, a want which alcohol can alone supply, as it stops for a time the waste of nerve-power, is often derived from the excesses of drunken parents.

Still further, the children of drunkards inherit various neuroses, such as hysteria, epilepsy, mania, ataxy, and different forms of paralysis; and a child begotten during drunkenness early falls a victim to either phthisis, or some deep-seated disease of the nervous system. Intemperance is perhaps the most formidable enemy to the safe assurance of life, and even ranks before phthisis in its deadly effects on the system. Organic ailments are by it originated, and organic weakness crystallised into disease. The degenerations of age are anticipated and precipitated by alcohol, and the dram-drinker is sure to have a shortened life. The man who carries his drink well and is 'never drunk' is in the greatest danger. Small doses of stimulants throughout the day, ended by a somewhat larger one at night, leave the system always charged with alcohol, and the excretory organs are continuously under its influence. The most searching inquiry should therefore be made as to the quantity taken each day, and the frequency of the dose. The medical examiner must be thrown on his own tact to discover from certain well-known indications whether the proposer is a drinker. Among these are the flushed face and nose, the tremulous tongue or hand, the relaxed skin, the eye, and the manner over-rapid and nervous, or subdued and sullen. Of all classes of the intemperate the habitual dram-drinker is the worst.

Diseases of the nervous system are eminently heritable, as epilepsy, general paralysis, and mania. Of 321 epileptics, one-third had epileptic parents. The children of such become diseased early, but it may be considered that after forty the liability is exhausted.

Insanity is commonly hereditary: about one in three or four has had a parent insane. The issue of one insane parent might be accepted if the age be 35 or 40, and the proposer free from any nervous affection.

PERSONAL EXAMINATION.—The medical examiner should ascertain the condition of the chief

organs of the body, especially the heart and great vessels, the lungs, and the kidneys.

Heart.—The size of the heart and the strength or weakness of its impulse should be ascertained. *Intermission* of heart-beat and pulse, if unaccompanied by other irregularities of rhythm, may not be of grave importance. If it be only a loss of beat once in twenty or thirty, it may be regarded as harmless, or referable only to an alteration in the innervation of the heart. It may not be always present, may be indeed absent for days or weeks, or be suspended during a feverish attack, or present only during some trivial alteration of digestion. *Irregularity* of heart-action is of different import. The heart will repeat a number of rapid beats, then pause, and lose one or several successively. The sounds are confused in character and run into one another, the impulse is diminished, and the interval lost or irregular. Feebleness is the predominant character. A heaving and displaced heart-beat is a common result of hypertrophy. The danger to life arises from the consecutive events of hypertrophy, dilatation of the heart's chambers, and valvular incompetence.

Murmurs may be audible over any of the valvular regions of the heart, and accompany either the first or second sound or both. The *characters* of a murmur—its softness, flowing, harsh or rasping sound—are *per se* no indications of its value or pathological import: a harsh or a loud murmur is often of a less serious nature than one more distant and less pronounced, as the power of the ventricle behind the obstruction is generally the cause of its loudness, and a moderate degree of hypertrophy is a compensating agent. If there be obstruction at an orifice, all symptoms of heart-disorder may be held in abeyance for years if only there is power to drive the blood through the obstructed valve. *Ephemeral* murmurs often give rise to doubts as to the safety of assurance—such as occur in the left subclavian region, when firmly pressed by the stethoscope, or in certain positions of the person examined, or in that portion of heart which is covered by the lung. They may be heard on deep inspiration only, and are temporary in character. They are not to be regarded as prejudicial to life (*see* HEART, Functional Diseases of). The *anæmic* murmur, soft, systolic, and blowing, is heard over the first part of the aorta or pulmonary artery. It is occasionally heard over the mitral region. It is generally associated with curable conditions; but it is not to be forgotten that fatty degeneration of the walls of the heart has been found in cases of prolonged anæmia. The rule is to defer such cases for a month or two.

The lesions most important to consider are those of the aortic and mitral valves.

Aortic murmurs may be single or double. The single murmur is probably obstructive, the valve being thickened and warty, and the coats of the vessel diseased.

In *aortic regurgitation*, recognised by a diastolic murmur, the greatest degree of ventricular hypertrophy occurs, and the heart attains an enormous size in compensatory efforts to maintain the systemic circulation against gravity, the open valves permitting the return of a large portion of the blood into the ventricle. The carotids are seen throbbing, and the radials present the well-known character caused by sudden recession of the blood-current called the water-hammer pulse. This form of

disease is among the most fatal of heart-affections, and is entirely uninsurable, the elements of durability being wanting.

Mitral murmurs.—It is now a well-ascertained fact that persons in great number having a marked mitral murmur may live to advanced age without presenting any symptoms, and therefore without the effects of heart-disease recognised as injurious to life; and of this the best medical authorities have recorded numerous instances. The first downward step in the fatal event of mitral disease is when the cavities of the heart begin to yield to the pressure of the regurgitated blood, and dilatation follows (*see* HEART, Dilatation of). The series of events is mechanical; and it may be stated that, so long as the muscular integrity of the heart's walls is maintained, the subject of the affection may enjoy fair health with ordinary precautions. The dangers to such a life would probably arise after middle life, at the period when degenerations of structure commonly commence. The rule of assurance-companies has till lately been to reject all such lives as present any form of mitral disease; but if a case present itself with murmur only, without great enlargement of the heart; if the ventricular contraction be strong and the murmur well pronounced; and if, in addition, it can be shown that such condition must have prevailed for a long time—say, from the date of one attack of rheumatic fever years previously; if the proposer has his other organs healthy and does not exceed thirty-five years of age, then it is safe to accept such a life with a considerable addition to the premium (10 to 15 years), or by securing that all the premiums should be paid up in a short term of years—say, eight or ten.

The most dangerous heart-cases are those indicating failure of muscular power, and aortic cases are more perilous than mitral. The presence of albumen in the urine should always be looked for in connection with disease of the heart. *See* p. 670.

Pulse.—The frequency of the healthy pulse varies with the constitution of the nervous system, and the posture, sitting or standing, of the individual. Its healthy beat might average 60 to 70; but a large range should be allowed for temperament and emotional causes, the very fact of its being examined giving rise to acceleration. The physician will therefore give time for its subsidence, or make a fresh examination on another day. A sustained frequent pulse may indicate fever, phthisis, or exophthalmic goitre. The fulness or incompressibility of a pulse, and a character of wiriness under the fingers, should be noticed. The latter may indicate sclerotic changes in the vessels, when the condition of the temporal and other arteries should also be examined.

Chest.—A careful examination of the lungs should be made by palpation, percussion, and auscultation, the dress being removed, and measurements taken by a tape at the level of the sixth rib. These vary in different individuals, and from 33 to 38 inches has been given by different observers as the average in adult males. The difference between extreme inspiration and expiration should not be less than two inches at the level of the nipple. It may be taken that the *mobility* of the chest is of more importance than its size. Attention should be paid to any undue flattening of the chest-walls, such as may have been caused by phthisis or old effusions.

Phthisis.—According to the Registrar-General,

one death in every eight is due to this cause. If the physical signs of phthisis are present the life cannot be considered insurable, except for very short periods, and even then on terms which would be rarely accepted by a proposer. However, as every condition of health has its insurance-price if we could appreciate its possible future with anything like accuracy, it is well to remember that phthisis is sometimes very chronic. Of these, fibroid phthisis and a well-defined single cavity in one lung are illustrations; but, if it were possible to accept them for the purpose of insurance, their chronicity should have been already shown by a long previous history, and the actual state of proposer should be without either fever or much wasting.

Hæmoptysis.—There is no question more frequently before the medical examiner than the influence of blood-spitting on the value of life. We have met with the following varieties:—

(a) After a run or strain in athletics, as rowing or lifting weights, a mouthful of fluid blood has been brought up, a few clots some hours, or next day, after; and then a total cessation of the symptom occurs, without any subsequent disorder of health.

(b) The patient having had cold or cough for a week or two, a 'few streaks' of blood mixed with phlegm have been brought up, or a spoonful of red blood in the morning on waking, and the symptom has recurred after an interval of days or weeks.

(c) Without acknowledged disorder of health, or cough, a robust or, it may be, a spare person may bring up a mouthful of fluid blood, dark, or it may be in clots, for a day or two, when it ceases, without any symptom of illness, but probably will return, some weeks or months afterwards.

(d) A copious blood-spitting, a cupful or pint, fluid at first, then clotted, possibly repeated in a day or two, with or without any manifest disorder of health.

Such are the most common descriptions of blood-spitting which are given us orally, or reach us as medical reports from examiners. As we are dealing with reports only, we do not mention the symptoms, such as bodily temperature, which should guide us if we had the opportunity of seeing the patient at the time.

(a) is the usual story of hæmoptysis from strain or injury, and may occur without any subsequent ill-health. It is common among the young and robust. Should an interval of months have elapsed since the occurrence, and the health remain good, and the absence of any physical signs of lung- or heart-disease be verified by examination, such lives may be accepted, with a small addition to the premium, especially if the applicant have passed thirty years of age.

(b) is the characteristic of commencing phthisis, and grave disorders of general health, as well as physical signs of lung-disease, will soon become manifest. The life is plainly not insurable.

(c) is probably of cardiac origin, or due to hæmophilia. That from heart-lesion is met with in two very distinct forms. The more severe is commonly due to mitral disease, especially stenosis, and occurs late in the history of disorders dependent on that cause; and evidence of venous congestion, and of dilated heart-chambers, will have generally been in existence long before a hæmorrhage into the lung takes place.

(d) is of not infrequent occurrence. A person

commonly under thirty-five will have brought up blood from the mouth on various occasions, fluid, but more commonly dark or clotted, and have but little disturbance of health. There is commonly no cough, nor any expectoration, and only slight dyspnoea may be complained of. The most careful examination will detect nothing wrong in the lungs, and the subjects have commonly large and well-made chests. There is no rise of temperature at or after the attack, and the nutrition of the body is perfect. The writer has examined very many such cases, and in all the only physical sign was a slight click with the systole at the apex or lower end of the sternum. He has watched many of them over a series of years, and found no more serious symptom than here stated. There is little doubt that they are chiefly due to mitral imperfection, and, as they may eventuate in serious disease, are not eligible for ordinary life-assurance. It might, however, be possible to accept some of them for very short periods at an advanced premium. See HÆMOPHTYSIS, p. 620.

Emphysema.—Proposers often present the physical signs of emphysema, especially at the bases of the lungs. The proposer may or may not be the subject of fits of asthma, but the breath is always short on exertion. The co-existence of bronchitis shown by *râles* of the dry, sonorous, or mucous character, most marked with expiration, is often found, and eventually few advanced cases remain unassociated with heart-failure. Cases of this kind, excepting those which present heart-symptoms, may be accepted with an addition to the premium, the amount of which will vary with the mildness or severity and the rarity or frequency of the attacks, and the degree of loss of elasticity in the lungs. The liabilities increase with age, and the premiums should be paid up before the proposer is much beyond middle life. A short occasional attack of asthma, without the characteristic physical signs, may not materially vitiate a life.

A liability to *bronchial attacks* manifests a delicacy of the air-passages, and is often observed in persons of a phthisical, gouty, or syphilitic family. Chronic bronchitis in the elderly is commonly found in emphysematous cases, and the gradual supervention of changes in the air-vesicles and chambers of the heart renders such lives precarious. They are, however, occasionally accepted for a short term, and with a considerable addition to the premium.

Pleural effusions, if existing, would prevent the acceptance of a life, but neither a contracted side from absorption of a former effusion, nor the marks of paracentesis for the evacuation of the fluid, if the recovery has been complete, and the lung has descended to nearly its former level, should forbid acceptance if the general health be good. It must be remembered, however, that many cases of pleural effusions are of tubercular origin.

Digestive tract.—The tongue and fauces should in all cases be inspected. The salivary glands should be free from hardness or enlargements. The fauces should be examined for marks of former ulcerations. The nostrils should be free from obstruction, and the voice not nasal. The stomach should be examined by palpation and percussion, as stricture of the pylorus, or dilatation, may be present, and if found would justify rejection of the life. The *liver* should not come below the ribs, and a breadth of about four inches represents the normal dulness from the lower ribs upwards. Inequalities on

the surface of the liver may mean cancer or cirrhosis or hydatids, and their presence would justify exclusion. Mesenteric tumours, fibroid, scrofulous, or malignant, are not admissible. Hardness in the right iliac fossa, especially with a history of former *appendicitis*, is also inadmissible. A history of recent attacks of *appendicitis* justifies the addition of an increased premium and in some cases the rejection of the life, unless the appendix has in the meanwhile been removed. Any of the following affections, if known to have existed, should be regarded with suspicion: *Hæmatemesis*, gastralgia with vomiting, hepatic colic, hydatid cysts, obstruction of the bowels, typhlitis or perityphlitis, and ascites. There are cases of *hæmatemesis*, generally in the female, or the result of strain or direct injury, which might be accepted, but only after years of perfect health have elapsed. *Jaundice* of former occurrence, if the attacks have been slight, would not forbid acceptance. *Biliary colic*, if the attacks have been severe or recent, would prohibit acceptance; but a former attack, with subsequent years of good health, need not imply rejection.

Dysentery which may have occurred in a hot climate, from which the proposer has been absent for some years, with good present health, need not disqualify, but a considerable extra premium will be required if the proposer returns to a hot climate.

All disorders of the *rectum*, except hæmorrhoids of a simple kind, are serious. Cancer, abscess, or the syphilomata, may be suspected if symptoms of pain or obstruction can be elicited. *Hæmorrhoids* need not disqualify unless they be of a severe form, or have recurred after operation, or presently call for surgical interference.

Genito-urinary organs.—Disorders of these organs are among the most important which affect the value of lives. They are often very insidious, as persons in a state of disease may present the appearance of perfect health. It is notorious that a man may have glycosuria or albuminuria, and neither know it himself nor exhibit in his appearance any evidence of the disorder. It is therefore imperatively necessary that the urine should be tested chemically in every case. This rule was formerly not adhered to, and many offices suffered in consequence; but it has now become a general practice, which has in some instances to be supplemented by a microscopical examination.

Hæmaturia of recent occurrence and *stone in the bladder* would forbid acceptance. *Dysuria* from stricture or enlarged prostate is an unfavourable condition, but there are mild cases of stricture which may be accepted with an addition.

Syphilis.—Syphilis affects the duration of life considerably, and is to be regarded not only from the length of time which has elapsed since the last attack and its cure, but from the nature and degree of the symptoms. The late Berkeley Hill believed that the curable cases get well in two years; the incurable may last for an indefinite time. For two years a person may expect a return of the eruption. Tertiary affections generally appear about five years after the primary affection. The rules for assurance may be thus stated: During the actual existence of any syphilitic disorder the proposal should be postponed. A man who has had syphilis in only the ordinary cutaneous and superficial form, and has been properly treated for it, may be accepted after a year has elapsed without symptoms. If he have had syphilis in the tertiary forms, he should

only be accepted if two years have elapsed since the latest symptom, and then with a small addition to the premium. Those who have had visceral syphilis affecting the brain, cord, liver, lungs, kidneys, &c., should be rejected.

Albuminuria is found in several chronic affections of the kidney, and in acute nephritis. It is also present in several acute inflammatory affections, with which we are not now concerned. Its presence should always be looked for. It is usually more copious after food and exercise, and its appearance in the urine is often intermittent, being absent at times for hours or even days. Acute albuminuria from exposure to cold and wet, and that which follows scarlatina, may disappear without leaving any organic change in the kidney, but in certain cases it recurs. If, however, some years have elapsed since its occurrence, and the proposer have enjoyed perfect health, the case may be accepted. In chronic cases, it is most commonly the result of some form of Bright's disease. There is, however, no doubt that albuminuria occurs in many persons without any other symptoms of disordered health, and may so continue for years. Concerning the importance of this there is much difference of opinion (see ALBUMINURIA). We should advise the following rules for practice:—

Albuminuria, formerly existing as a result of acute nephritis or scarlatina, with a return to ordinary diet and an interval of perfect health for years, need not disqualify a proposer. Cases of albuminuria existing, and known to have existed for years, in persons of otherwise perfect health and good family history, may be assured for a short period—say, of five years—with an addition to the premium, and may come up for examination again at the end of that period. Cases of albuminuria with any of the symptoms of *chronic Bright's disease*, with any cardiac, gouty, or rheumatic complication, or any suspicion of intemperate habits, should be declined. For the tests for albumen, see ALBUMINURIA. *Casts* in the urine confirm the diagnosis of organic disease of the kidneys.

Glycosuria.—Sugar may be present in the urine apart from diabetes mellitus, of which all the symptoms may be wanting. Glycosuria is often a temporary condition, and may disappear leaving no ill effects; but it is always to be regarded with suspicion, and its presence alone should forbid the acceptance of a life. It is common in obese persons, gross feeders, and in the gouty habit; and its subjects may have no suspicion of its existence, and feel in perfect health. The urine should therefore be always examined for sugar. Diabetes mellitus is a permanent condition, and the mortality from it increases with age up to sixty or seventy years. Males are twice as liable as females. It is difficult to estimate its duration, as dietetic measures can much retard its progress; but the prognosis, on the whole, is bad, as the liability to cerebral affections, to phthisis, carbuncle, and other fatal complications is very great. Its subjects, therefore, must be excluded from life-assurance. Glycosuria will forbid the acceptance of a proposer while it exists; but if there be no gout, and if all traces of sugar have disappeared for years, a calculated addition might be made to the premium (see GLYCURONIC ACID). In glycosuria the quantity of urea is generally increased. A high specific gravity, even above 1030, is no evidence of sugar in the urine, unless a chemical examination have

proved its existence. For the tests for dextrose, or grape-sugar, see *DIABETES MELLITUS*.

The excess of *phosphates* in the urine is generally temporary, and often due to anxiety and waste of nerve-power. It is recognised by a cloudiness on boiling, which is entirely cleared by the addition of a drop or two of nitric or acetic acid. It forms no obstacle to the acceptance of a life.

The presence of alkaptonuria implies no additional risk. See *ALKAPTONURIA*.

Disease of the *testicle*, tubercular or malignant, disqualifies for assurance. *Hydrocele* and *varicocele* may *per se* be regarded as harmless.

Female organs.—Metritis, pelvic inflammation, and ovarian disease, are doubtful cases for acceptance. Women who have had repeated abortions, puerperal hæmorrhages, eclampsia, or a necessity for obstetrical operations, are not eligible unless the menopause has been favourably passed. During a *first pregnancy*, it is well to defer assurance till after a safe confinement. Lactation is no bar to acceptance. The average duration of life in women is longer than in men, and by latest returns is shown to be increasingly so.

Nervous system.—Diseases of this system, as cerebral softening, locomotor ataxy, hemiplegia, paraplegia, and aphasia, disqualify a proposer. Local paralysis of the motor muscles of the eyeball, and ptosis, unless congenital, would lead to suspicion of brain-disease, and would not be acceptable. *Paralysis of the facial nerve* (Bell's), when purely local, and free from complications with disease of the ear and disorder of the fifth or other nerve, need not disqualify. *Paralysis* from lead-poisoning is always serious, and the liability to diabetes and deep disorders of the nervous system should not be forgotten. A recognition of the blue line on the gums would lead us to decline the life. *Neuralgias* of branches of the fifth nerve may not disqualify unless they be associated with cerebral symptoms, or be the result of syphilis or exostosis. *Vertigo* of a severe kind, associated with symptoms of *Ménière's* disease, would disqualify; and even its more transient forms, if often repeated or associated with gout, may be a bar to acceptance. *Trembling of the hands* may arise from organic disease or from the abuse of tea, tobacco, or alcohol. If from the latter cause, we may expect the tongue to be also tremulous. Although it may be temporary, its presence should cause grave suspicion as to habits.

The more severe forms of *epilepsy* must forbid acceptance, unless ten or fifteen years have elapsed since the last attack, with an interval of perfect health, and even then an addition should be made to the premium. There is a mild form appearing in early life, which can generally be traced to such causes as overwork or too close application to study, and where the heredity is absent; if years have elapsed without its recurrence, and the proposer has passed thirty and has engaged in the active work of life without symptoms of nervous disorder, and is strictly temperate, the life may be accepted with an addition of five to seven years.

Height and weight.—The relative proportion of height and weight is important in estimating the probabilities of future disease in a proposer. In estimating over-fatness, if the chest and shoulders be large and the abdomen moderate in size, the condition is less important than if the abdomen were large and pendulous. In stout persons, therefore, the circumference of chest, abdomen, and

limbs should be given, and flabbiness or firmness of tissue is to be considered, while habits as regards exercise, food, and stimulants should be carefully inquired after. The *dangers* of obesity are weakness of the heart or ultimate fatty degeneration of that organ. In a large proportion of these cases, fatty degeneration has affected the liver, and atheromatous alterations take place in the coats of the arteries, which lead to their ultimate rupture and consequent hæmorrhages. Obese persons are also worse subjects for fevers and accidents than are the spare and muscular, their power of recovery being lowered from feebleness of circulation. For these reasons the very obese are scarcely subjects for life assurance, although occasionally, if their habits be moderate, they may be accepted with an addition. On the other hand, the existence of excessive *leanness*, which may be the result of phthisis, diabetes, or various other wasting disorders, demands a careful examination. Most companies have tables of relative heights and weights, but a wide margin must be left for individual variations. One is appended which the writer has found sufficiently accurate:—

Height in inches.	Weight.		Height in inches.	Weight.	
	st.	lbs.		st.	lbs.
63·0	8	13	70·0	12	4
63·5	9	2	70·5	12	8
64·0	9	5	71·0	12	11
64·5	9	8	71·5	13	1
65·0	9	11	72·0	13	5
65·5	10	1	72·5	13	9
66·0	10	4	73·0	13	13
66·5	10	7	73·5	14	3
67·0	10	10	74·0	14	7
67·5	10	14	74·5	14	11
68·0	11	3	75·0	15	1
68·5	11	7	75·5	15	5
69·0	11	10	76·0	15	9
69·5	12	0			

Claims.—On the death of an assured life a claim is sent in to the office by the legal owners of the policy. This is accompanied by a certificate from the registrar of the district in which death occurred, and in some cases from the medical attendant. The practitioner who has to certify the cause of death cannot be too definite in his statement, nor too careful to avoid the use of terms which express only the symptoms and not the disease which proved fatal. Thus *dropsy* is common to diseases of the heart, liver, kidney, and other organs, and should not be employed; and for the same reason *hæmorrhage* and *diarrhœa*, which are common to many affections, should not be used. *Gastritis*, when certified as a cause of death, should always excite suspicion. The writer has known it used to conceal irritant poisoning and intemperance. A sudden attack of persistent vomiting with diarrhœa, leading within a week or two to a fatal issue, should not be received without careful inquiries as to the assumed cause of death. *Syncope*, which may represent the final stage of many diseases, should not be used. *Childbirth* is often used to cover other affections, such as phthisis, and should be limited to incidents proving fatal at or soon after a confinement.

We have also occasionally to consider whether the death of a proposer has been due to diseases

which must have existed at the time when the life was accepted, and therefore whether the statements made in the proposal as to the previous state of health and habits of a proposer were strictly true. If not true, the claim could not be maintained. There is here scope for all the acumen of the medical adviser of an Insurance Office.

It is believed that the practising physician will find in this article sufficient data to guide him in the selection or rejection of most lives offered for assurance. It is not possible to lay down specific rules for the amount of additions to the premium which it will occasionally become the duty of the medical examiner to advise. He may either rate a life at so many years older, or adopt some of the other methods by which the company may be secured against loss—as paying up all premiums within a given number of years, or deducting a portion of the sum to be paid by the company if death occur within a certain time, or making the sum payable at a certain age (endowment). Although on all these questions of finance the medical adviser can only recommend, his opinion will be highly useful to the company, with whom the ultimate decision will rest.

LIGHT, Therapeutic Effects of.—See SKIN, Tuberculosis of.

LIGHTNING, Effects of.—SYNON.: Fr. *Les Effets de la Foudre*; Ger. *Blitzschlag*.

The effects produced by lightning differ only in degree from those produced by the discharge of static electricity, generated in the laboratory. With a Leyden jar of sufficient size a small animal may be killed, and in larger animals the effects of shock and local injury may be produced. By lightning a person may be killed outright, and a *post-mortem* examination may reveal no lesion whatever. The mode of death in these cases seems to be by the shock to the brain and nervous system generally. Effects not distinguishable from ordinary concussion of the brain may be observed, and the person struck may remain insensible, with slow respiration, scarcely perceptible pulse, and dilated pupils, for periods varying from a few minutes to more than an hour. This may be followed by complete recovery; or there may remain paralysis of the limbs, usually the lower, or occasionally derangements of the special senses—blindness, a metallic taste in the mouth, noises in the ears, and an odour in the nose. The brain may be more or less permanently affected, and delirium, mania, and loss of memory may occur as results of the lightning-stroke.

Various objective phenomena have also been observed. The electricity on its way through the body may produce a number of mechanical effects. Wounds like those produced by a blunt stabbing instrument may mark the points of entry and of exit; bones have even been broken, the *membrana tympani* has been ruptured, and internal viscera have suffered in a similar way. Patches of erythema, urticaria, superficial ecchymoses, and scorplings of the surface having a curious tree-like and branched arrangement, have all been described; and this last phenomenon has apparently given rise to the assertion that delineations of trees standing in the neighbourhood of the accident have been traced photographically on the body of the victim. Lightning is apt to be attracted by any metal worn about the body. Watch-chains are frequently broken

and fused, and by the intense heating of these metallic conductors the clothing has been set on fire. Watches have been broken and partially fused, and have forcibly burst through the pockets in which they were contained. Steel articles, such as pocket-knives, have been rendered magnetic. The clothing is sometimes burnt and torn to a great extent, and strong boots have been found burst open, or thrown off the feet to a distance, or nails in the soles have been driven out of them.

The remote effects of lightning are due to the mechanical injuries produced by it. Permanent paralyses may result from injury to the nerves; and inflammatory action may be set up by the injury inflicted on internal or external parts. One case is recorded in which the whole of the hair on the head and body, as well as the nails of both hands, came off after a lightning-stroke. It has been asserted that *rigor mortis* does not occur in persons killed by lightning, and that the blood remains fluid for a very long time after death, but neither of these facts has been substantiated.

TREATMENT.—The treatment of those who have been struck by lightning consists in first rousing and keeping up the respiration and circulation. The cold douche is often of great value; and this, combined with friction of the limbs, warmth to the extremities, and the administration of stimulants, either by the mouth or in the form of enemata, would seem to be the measure best calculated to restore the suspended animation. Secondly, special injuries must be subsequently treated according to their nature. See RESUSCITATION.

G. V. POORE.

LIPIK (LIPPIK), in Slavonia.—Thermal mineral saline waters, with iodine. See MINERAL WATERS.

LIPOMA (λίπος, fat).—A fatty tumour. See TUMOURS.

LIPPITUDO.—Marginal blepharitis. See EYE, AND ITS APPENDAGES.

LIPPSRINGE and INSELBAD, in Germany.—Earthy waters. See MINERAL WATERS.

LISBON, West Coast of Portugal.—Warm, moist climate, with very variable temperature. Mean temperature in winter, 54° F. Prevailing winds, N.E.—S.E. in spring. See CLIMATE, Treatment of Disease by.

LISDOONVARNA, in Ireland.—Sulphur-waters. See MINERAL WATERS.

LITHÆMIA (λίθος, a stone; and αἷμα, the blood).—See URIC ACID DIATHESIS.

LITHONTRIPTICS (λίθος, a stone; and τριβω, I wear away).—SYNON.: Fr. *Lithontriptiques*; Ger. *Steinauflösende Mittel*.

DEFINITION.—Lithontriptics are therapeutical measures used for the purpose of dissolving calculi in the urinary tract.

ENUMERATION.—The chief lithontriptics are: Water, Potassium, Lithium, Borax, Phosphate of Sodium, Soap, Lime-water, Nitric Acid, Phosphoric Acid, Hydrochloric Acid, Sulphuric Acid, Piperazine, and Mineral Waters, such as those of Contrexéville and Wildungen.

ACTION.—Lithontriptics dissolve stones in various ways. Some of them possess a simple sol-

vent action, as in the case of water. Others unite with the calculi so as to form a more soluble compound, as in the case of the union of potassium or lithium with the uric acid of a calculus, producing urate of potassium or lithium, which is more soluble than uric acid itself. In the case of phosphatic calculi, diluted nitric acid combines with the bases of which they are composed, to form a more soluble compound.

USES.—Lithontriptics may be employed for the purpose of dissolving calculi either in the kidney or in the bladder. They may either be taken internally, so as to act upon the calculi through the medium of the urine; or be injected directly into the bladder. This latter treatment can only be adopted in the case of a vesical calculus, and is inapplicable in the case of a renal calculus. The most useful of all lithontriptics is water, especially distilled water. When this is taken in large quantities, the urine becomes very dilute, and small calculi may be partially dissolved, so as to be reduced in size and ejected through the natural passages. If the calculus is composed of uric acid, salts of potassium or lithium are the best remedies for internal administration, the urates of these bases being more soluble than the urate of sodium. Piperazine is a solvent of uric acid, twelve times as powerful as lithium carbonate. It has been used as a lithontriptic both internally and as a local injection into the bladder. In the case of phosphatic calculi, acid remedies are employed instead of alkaline; but it is exceedingly difficult to render the urine acid by means of acids given by the mouth, unless they are administered in quantities likely to derange the digestion. In place of mineral acids, benzoic acid and benzoate of ammonium have been employed, as benzoic acid passes out of the body in the form of hippuric acid, giving an acid reaction to the urine. On account of this difficulty, acids have been directly injected into the bladder, in order to act directly upon the stone; for which purpose nitric acid, largely diluted, is the one which has been most generally employed. This procedure, however, is now rarely had recourse to, as it is much easier to crush the stone by mechanical means. The two most important springs for the treatment of renal or vesical calculi are Contrexéville and Wildungen. The waters of both of these places contain carbonate of iron, which appears to aid their action.

T. LAUDER BRUNTON.

LITHOPÆDION.—See CONCRETIONS.

LITHURIA (λίθος, a stone; and οὐρον, the urine). A condition in which a deposit of uric acid or urates takes place in the urine. See LIVER, Functional Diseases of; URIC-ACID DIATHESIS and URIC-ACID CALCULUS; and URINE, Morbid Conditions of.

LITTLE'S DISEASE.—See CEREBRAL PLEGIA.

LIVER, Diseases of.—The diseases of the liver will be considered in the following order:

Abscess, p. 882.

Acute Yellow Atrophy, p. 885.

Amyloid Disease, p. 886.

Chronic Atrophy, p. 887.

Cirrhosis, p. 887.

Cysts, p. 890.

Enlargements, p. 891.

Fatty Disease, p. 891.

Functional Disorders, p. 892.

Gangrene, p. 893.

Hydatid Disease, p. 893.

Inflammation and Active Hyperæmia, p. 896.

Malformations, p. 898.

Malpositions, p. 899.

Morbid Growths, p. 899.

Syphilitic Disease, p. 901.

Tuberculosis, p. 903.

The following articles will be found in their alphabetical position in other parts of the Dictionary: ACTINOMYCOSIS; BILE, Disorders of; BILIARY FISTULA; BILIOUS; CHOLAGOGUES; CHOLESTERIN; CONCRETIONS; GALL-BLADDER AND BILE-DUCTS, Diseases of; GALL-STONES; HÆMORRHAGE (including HÆMATEMESIS); PAIN IN VISCERAL DISEASE; PHYSICAL EXAMINATION; PORTAL OBSTRUCTION; PORTAL THROMBOSIS.

LIVER, Abscess of.—SYNON.: Hepatic Abscess; Fr. *Abscès du Foie*; Ger. *Leberabscess*.

Abscesses of the liver are divisible into two classes: (1) tropical abscess; (2) other forms of pyogenic infection, including those resulting from pyæmic conditions, especially such as arise from typhlitis and surgical operations or affections about the rectum; suppurating hydatid cysts and other parasites; traumatism, especially blows on the liver; gall-stones; and pylephlebitis. Tropical abscess will be alone considered in this article. Suppuration complicating other conditions is considered elsewhere. See pp. 565, &c.

Tropical Abscess of the Liver.—ÆTIOLOGY.—The association of abscess of the liver with dysentery has long been recognised, and the more the subject is investigated the more constant is this association found to be. So much is this the case that some recent writers incline to regard the terms 'tropical abscess' and 'dysenteric abscess' of the liver as synonymous. It may safely be asserted that in 75 per cent. of cases of hepatic abscess a history of some degree of dysentery—not necessarily of a very urgent character—can be elicited. It must be recognised, however, that in this association the order of events is not always the same: usually the dysentery is antecedent to the hepatitis; sometimes the diseases appear to be co-incident; more rarely the hepatitis appears to precede the dysentery; and in not a few cases the clinical manifestations of the two conditions alternate. The advocates of the ætiological identity of these diseases suggest that in a proportion of cases in which dysentery is not a feature either before, during, or after the occurrence of abscess, the pathological drama has not been played out. They argue that, just as dysentery may exist without hepatitis, hepatitis may exist without dysentery. Whatever may be the exact relationship between these diseases—a relationship succinctly expressed by the term 'hepatic dysentery'—it is certainly a very intimate one, and one which should always be borne in mind in the diagnosis of hepatic abscess, as well as in the prognosis of dysentery; and it should also be borne in mind that the abscess may not develop till months after the dysentery has been recovered from, and the patient perhaps has left the endemic area.

The most potent circumstance in predisposing to hepatic abscess is residence in a hot climate, especially if the heat is combined with humidity and, possibly, malaria. There are exceptions, but, speaking generally, liability to this form of abscess increases *pari passu* with these conditions. Intemperance in eating and drinking; lazy, luxurious habits; bad food; hardship and exposure, such as are incidental to a soldier's life in time of war; hot, close, and overcrowded barracks; and insanitary conditions in general have a marked though predisposing influence. Men are more subject to it than women, adults than youths; children seem to enjoy an almost absolute immunity. Race has undoubtedly some influence, but how it acts—whether in consequence of peculiarities of habit, acclimatisation, or specific racial idiosyncrasies—has not been adequately determined. It is certain that liver-abscess is much more common in Europeans residing in hot climates than in the ordinary natives, but natives who adopt the habits of Europeans as regards alcohol and rich living are said to approach the European in liability to the disease.

Among the circumstances which determine the formation of abscess in persons predisposed are, above all, chills of the surface such as arise from rapid alternations of heat and cold, from sitting in draughts in wet clothes, from bathing in cold water, or sleeping without adequate clothing. A blow on the liver, a bout of drinking, or a surfeit, is often the starting-point of the disease.

ANATOMICAL CHARACTERS AND PATHOLOGY. Tropical abscess of the liver may be single or multiple, and it may vary in size from a minute collection of pus to an enormous sac containing many pints of fluid, and occupying a large extent of the liver. When a section of a liver in a state of incipient suppuration is made, one or more circular patches, greyish-yellow or otherwise altered in colour, and surrounded by an area of congestion, are revealed. Abscess is formed by the breaking down of one of these patches, liquefaction commencing in the centre. Frequently two or more neighbouring patches coalesce. When the abscess has attained any size its walls are found to be very irregular, their inner surface being coated usually with a yellowish tenacious purulent material lying on a thin zone of more or less infiltrated liver-tissue—the abscess-sac—which in its turn is surrounded by a hyperæmic zone; beyond this the liver-tissue may be fairly healthy. Around and, so to speak, in the walls of the principal focus of suppuration a number of minute abscesses may form, and it is by the bursting of these into the main cavity, and the necrosis of pieces of intervening tissue, as well as by the slower process of purulent and molecular disintegration of its walls, that the cavity enlarges. The contents vary considerably: usually they are of a chocolate-brown colour, and have a thick gummy consistence tending to become gelatinous on cooling. The odour too is peculiar. Not infrequently lumps of necrosed liver-tissue or clots of blood are found floating in the fluid, which may also be streaked with blood, bile, or a yellow mucoid-looking pus of a paler colour. Occasionally the pus is more fluid, and may have the appearance of ordinary pus; rarely it is thin, watery, or grumous. It frequently contains a variety of micro-organisms, including the colon-bacillus, but in not a few instances the bacteria of pus are absent. It is further characterised in a certain proportion of

cases by the presence of a protozoal organism—the *Amœba coli*. See DYSENTERY, p. 426.

When the abscess is single its most usual situation is towards the back part of the right lobe, but it may occupy the left lobe or any other part of the gland. When abscesses are numerous, they are scattered throughout the liver, especially near the peritoneal surfaces.

Death may occur before the abscess ruptures; rarely it becomes encysted or absorbed; usually it makes its way to the surface of the organ and, after adhesions have been formed between opposing serous surfaces, opens on the surface of the body or into some of the neighbouring viscera. The most usual direction in which rupture occurs is into the right lung, next in frequency the intestinal tract, less frequently the surface of the body, and rarely into the pleural or peritoneal cavities or into the pericardium, gall-bladder, inferior vena cava, or pelvis of the right kidney. Rupture into the pericardium or inferior vena cava is necessarily and speedily fatal, but recovery has followed surgical interference after the rupture of a hepatic abscess into the peritoneum. Recovery may sometimes speedily ensue after rupture of the abscess, especially if it opens into the lung or intestinal canal; but in this event, in the majority of instances, the necrotic process is not arrested, and the patient sinks after perhaps a long illness. Recovery after surgical operation, even in the case of very large abscess, is often remarkably rapid, a great cavity of many ounces capacity healing up perhaps in a week or two.

Of the intimate pathology of hepatic abscess little, if anything, is known. By the discovery of the *Amœba coli* in connection with this disease and dysentery, the question seems to have entered on a promising field (see pp. 426, 428). It has been shown that the amœba occurs not only in the hepatic discharges, but also in the tissues surrounding hepatic abscess. That it is not invariably pathogenic is proved by its being sometimes present in the normal feces of apparently healthy individuals.

With reference to the association of dysentery and hepatic abscess, it ought to be mentioned that in some epidemics of dysentery abscess is of more frequent occurrence than in others; and this has been remarked, not only in epidemics in the tropics, but in epidemics occurring in Europe. In many of the latter hepatic abscess is almost unknown, but in others it is not so rare, as in the Dublin epidemic of 1818. Manifestly there is a specific element common to certain types of dysentery and hepatic abscess; but what this is, and how it operates, has not been determined. At one time it was held that the abscess was caused by the absorption of pus by the portal vein from the dysenteric ulcers, and from suppurating phlebitis which was supposed to be present in the intestinal radicles of that vessel. But no such phlebitis was demonstrated; and, moreover, it has been contended that as in certain instances the hepatitis may precede the dysentery, it therefore could not be caused by the latter. Further, as hepatic abscess is by no means a frequent sequela of gastric ulcer, of typhoid fever, or of tubercular or malignant ulceration of the intestine, the ulceration of the bowel in dysentery cannot *per se* be regarded as the cause of tropical abscess of the liver.

SYMPTOMS.—Sometimes these are fairly acute,

but in the great majority of cases they are of an extremely subdued and insidious character, so that sometimes the first intimation of the presence of abscess in the liver is its rupture into the lungs or intestine, and a discharge of the peculiar chocolate-coloured pus. Very often the symptoms amount to little more than feelings of ill-health, vague uneasiness about the region of the liver, and a state of low irregular feverishness. Temperature in the morning may be but slightly, if at all, above the normal, rising during the day to 101° or 102° ; or there may be spells of complete apyrexia or, occasionally, of high fever. Profuse sweating, particularly during sleep, is generally very marked. Slight feelings of chilliness occur from time to time, and in a few cases sharp rigors are met with; but too much importance must not be attached to their absence. The complexion may be muddy, and the sclerotics slightly yellow; the urine, though often loaded and dark, is seldom icteric; marked jaundice is rare. The temper is generally very irritable, and the spirits depressed. The tongue is sometimes coated; at other times it is clean. Appetite is usually poor; but occasionally it is fairly good. Vomiting may occur, especially if the left lobe of the liver is involved. The bowels may be confined; generally they are loose or irregular, often dysenteric. A short dry cough and some dyspnoea are not uncommon. The decubitus is usually dorsal or on the right side. In some cases pain of a cutting character in the region of the liver is a distressing symptom, and is regarded as evidence of perihepatitis, and the formation of adhesions between the peritoneal surfaces. In other cases the pain is of a very subdued type—merely a sense of weight and uneasiness; but it is usually intensified by pressure or percussion or smart compression, and it is often observed that percussion over the lower part of the abdomen may cause pain not where the blow falls, but in the region of the liver. Firm pressure on the liver often gives rise to a feeling of nausea or faintness. Pain in the right shoulder or scapula is one of the classic symptoms of hepatic abscess, and is regarded as an indication that the mischief is in the neighbourhood of the diaphragm. The abdomen is generally on inspection seen to be motionless and full. The liver is enlarged, but not always to a great extent; the enlargement may be upwards, a more significant sign than when it is enlarged in a downward direction. There may be a general bulging of the right hypochondrium, and obliteration of some part of one or two intercostal spaces, with a degree of œdema or even redness of the integuments. In wasted patients with normal livers the epigastrium should be concave when they are lying down, but in abscess of the liver it is often flat or even bulging, and this is more apparent when the patient is made to stand up; this appearance, with fever and tenderness, is always a suspicious symptom. Friction or crepitation may be heard at some part of the base of the right lung; the presence of these indicates proximity of the abscess to the diaphragm; and if, in addition, the *Amœba coli* is found in the sputum, rupture of the abscess into the lung is impending. When this occurs, a thick, gummy, chocolate-brown pus—quite pathognomonic in appearance, and yielding the reactions of bile when tested chemically, and exhibiting granular and degenerated liver-cells under the microscope—is brought up. In consequence of the persistent coughing after the abscess has opened and partially

emptied, there may be much hæmorrhage from its walls, and a very bloody sputum; so that the great bulk of the expectoration may be blood, with here and there only a streak or pellet of the chocolate-brown pus. This appearance is very apt to deceive the unwary, and to lead to a diagnosis of pulmonary hæmoptysis. The stethoscope may detect approximately the point of entrance of the abscess into the lung, and occasionally it reveals peculiar and very loud bruits, synchronous with the pulse somewhere about the upper border of the hepatic area, and sometimes of a to-and-fro character. These bruits probably arise from a to-and-fro play of air out of and into a partially empty but uncollapsed abscess-sac through a narrow sinus, and are produced by the jog communicated to the inflated abscess-sac by the systole of the ventricles. Should the abscess open into the bowel, there may be one or two loose stools of a similar chocolate-brown character; and in a case of suspected abscess of the liver the physician ought always to bear this in mind, and inspect any loose motions reported to him. Rupture into the stomach may be followed by vomiting; rupture into the pericardium or peritoneum, by sudden collapse.

DIAGNOSIS.—This is often a matter of great difficulty, even to the most experienced, and at times only to be settled by the development of events, or the use of the aspirator. An excellent rule for the practitioner in countries in which hepatic abscess is endemic is as follows: Whenever persistent ill-health is associated with a low degree of fever, and symptoms—no matter how trifling—referred to the abdomen, which cannot be readily accounted for, suspect abscess of the liver, and examine the organ daily with this possibility in view, and inquire carefully for a history of dysentery. It must be borne in mind, too, that the dysentery may have been very trifling, called perhaps diarrhoea, and that it may have occurred several months before the health began to break down. The significance of enlargement of the liver, localised hepatic swelling, pain, tenderness, a fixed and motionless abdomen, rigors, and a hectic temperature following dysentery can hardly be misunderstood. But it is seldom that in the early and more hopeful stages of abscess the indications are so unequivocal; indeed it may be, and often is, entirely overlooked, and not discovered until it has burst into lung or bowel, or until it is found on the *post-mortem* table. The presence of pneumonic crepitus about the base of the right lung in liver-cases is often misinterpreted; rightly understood, it is a most valuable confirmatory sign, especially if it is limited to a small patch. Sometimes the periodicity of the fever, the severity of the rigors, and regular procession of pyrexia and diaphoresis in hepatic abscess, lead to a diagnosis of ague; but the impotence of quinine to cure the fever, and the absence of the *Plasmodium malarie* in the blood, and of splenic enlargement—which is nearly always present when the liver is affected in malarial hepatitis, which rarely ends in abscess—ought to awake suspicion. When in a malarial subject there is a history of dysentery, and both liver and spleen are enlarged, diagnosis in the early stage of hepatic abscess is nearly impossible without the aid of the aspirator. In any case where grave doubt exists, where fever is persistent, and the patient is manifestly losing ground, exploration with a medium-sized aspirator-needle must not be delayed. This trifling operation, if attended with

any risk, is infinitely less dangerous than procrastination. With proper precautions it is not a dangerous proceeding; so far from doing harm it has often a markedly curative effect in cases of hepatitis, even when there is well-marked local bulging. As an encouragement to early recourse to the aspirating needle, it ought to be borne in mind that hectic fever may occur in hepatitis before the formation of pus, and even in cases in which pus never does form; and the whole trouble which otherwise might have ended in abscess may rapidly subside after exploratory needling. In exploring the liver with the aspirator, in the absence of definite localising indications, the needle ought to be inserted in the first instance about the seventh or eighth interspace in the anterior axillary line; if pus is not found here, a second and third puncture should be made, the needle being driven in to its full extent if necessary, in front just below the ribs a little to the inside of the nipple-line, and again behind in a line with the angle of the scapula well below the edge of the lung. *See PARACENTESIS.*

PROGNOSIS.—It is impossible in the present state of medical knowledge to say how dysenteric hepatitis will terminate, whether in resolution or abscess. Should the latter form, provided it is single and opened soon and effectually drained, the prognosis is fairly good; quite 50 per cent. recover. If left too long or allowed to open of itself, the prognosis is bad, though by no means hopeless. If two or more abscesses are present, the chances of recovery are proportionately diminished; and if there are many suppurating points scattered through the liver, death is inevitable. If after operation the temperature quickly becomes normal and keeps so, prognosis is favourable; but if, on the other hand, after operation there is a distinct evening rise and a continuance of the hectic fever, the worst may be apprehended.

TREATMENT.—Hepatitis threatening abscess ought to be treated by absolute rest in bed, low diet, and, in the absence of diarrhoea or dysentery, saline aperients, such as sodium sulphate. The right side ought to be covered with a large hot frequently renewed poultice, a foot in breadth and three feet in length, which should pass from beyond the middle line behind to beyond the middle line in front. If there is dysentery, a thirty-grain dose of ipecacuanha should be given, and repeated as in ordinary dysentery (*see DYSENTERY*). In the absence of intestinal trouble, chloride of ammonium in twenty-grain doses every six hours is sometimes exhibited with advantage. Quinine is indicated in malarial complications.

Symptoms not improving, exploration with the aspirator must not be too long delayed. If pus is found the abscess should be opened forthwith, thoroughly drained, and treated on Listerian principles. It may be remarked that in no surgical affection is it more necessary to observe the great surgical principles of early opening, free drainage, and perfect asepsis. By these means the mortality in this affection has of late years been enormously reduced, and a diagnosis of liver-abscess is now no longer to be regarded, as it was in former days, as almost tantamount to sentence of death. The opinion of the physician is sometimes asked as to the propriety of making an external opening in the case of an abscess discharging through the lungs or intestinal canal, or from an inefficient sinus in the walls of the chest or abdomen. A good rule to observe in such

a case is this: If the patient is improving, fever absent, and discharge lessening, do not counsel interference; if, on the other hand, hectic fever persists, the discharge increases or does not diminish materially, and the patient continues to lose ground, advise operation. If there be doubt about which course to advise, recommend change of air, which has sometimes a wonderful influence in wavering cases in inducing healing. Should fever and ill-health persist after the abscess has been freely drained, and the drain, though effective, give vent to very little discharge, suspect the presence of a second abscess, and advise further exploration, and—if pus is found—further operation. Recovery has followed after several abscesses have been so treated in the same individual. If the temperature keeps up after all abscesses have been opened, and discharge from the drainage tube is profuse, it is an indication that the necrotic process is still going on in the liver; the prognosis is then most unfavourable. Gangrene sometimes sets in around the operation-wound, and is almost invariably fatal.

When pus has formed, the diet ought to be fairly liberal; but overfeeding and overstimulation are under all circumstances to be carefully avoided.

PATRICK MANSON.

LIVER, Acute Yellow Atrophy of.—**SYNON.**: *Fr. Atrophie Jaune Aiguë du Foie; Ictère Grave; Ger. Acute Atrophie der Leber.*

DEFINITION.—An extremely acute inflammation of the liver, due to some unknown poison.

ÆTIOLOGY.—Acute yellow atrophy is a rare disease. It may occur at any period of life, but is most prevalent between the ages of 20 and 30. It is twice as common among women as among men; pregnant women are especially liable to it (*see PREGNANCY, Diseases of*). Emotional disturbances, such as grief and trouble, and bad hygienic conditions, have been thought by some to predispose to this disease. It is occasionally preceded by syphilis and acute alcoholism, and may supervene upon cirrhosis of the liver. It was originally attributed to phosphorus-poisoning, which causes a closely allied condition.

ANATOMICAL CHARACTERS.—The appearances are those of an acute necrosis, combined with slight reactive inflammation. The liver is small: in extreme cases it may weigh as little as nineteen or even thirteen ounces. It decreases in all diameters, but often irregularly. The capsule is wrinkled, and the organ is limp and flabby, not unlike collapsed lung (Rolleston). On section the outlines of the lobules are almost, if not quite, lost, and the surface is of a bright yellow-ochre colour broken by reddened patches. The yellow represents the early and acute stage of the disease; the red represents the later changes, in which most of the liver-cells have disappeared, the colour being partly due to distension of blood-vessels. By these signs the liver may be readily distinguished from that in phosphorus-poisoning, in which condition the liver is large and contains large quantities of fat. The liver in acute yellow atrophy contains very little fat. The gall-bladder and bile-ducts are either empty or contain a grey mucus. Under the microscope, the liver-cells are seen to be shrunken, granular, and bile-stained. Around both intra- and interlobular veins are a number of round cells, probably leucocytes. Charcot-Leyden crystals, as

well as crystals of leucine and tyrosine, have been found, especially when the liver has been preserved for some time. Double parallel rows of cubical cells, such as are seen in some forms of cirrhosis, are generally present.

Bacteria have been observed in the liver, but their pathological significance is doubtful. The spleen is enlarged and soft in the great majority of cases. The stomach and alimentary canal present dark red or tarry contents, the outcome of hæmorrhage; the tubular glands of the stomach are filled with fatty degenerated epithelium. The muscular tissue of the heart shows likewise granular or fatty degeneration; and the tubules of the kidneys are filled with epithelium in various stages of fatty degeneration.

SYMPTOMS.—Acute yellow atrophy is commonly preceded for some days or weeks by a simple jaundice, in which nothing peculiar can be made out. Delirium and convulsions then suddenly set in, followed by deep coma, stertorous breathing, dilated pupils, and increased jaundice. During the first part of the disease the pulse is natural or reduced in frequency, but with the appearance of the convulsions and delirium it rises to 120 or 130, becoming very feeble. The urine is normal in quantity, allowing for the vomiting, and bile-stained, and usually contains leucine and tyrosine. In some cases it is necessary to evaporate the urine to a concentrated condition to detect these. The amount of urea excreted is small (*see* LEUCINE; and TYROSINE). There is almost always constipation, the stools being at first pale, afterwards black from admixture of blood. Vomiting is very constantly present; at the end of the disease the vomit consists of a black coffee-ground matter. The tongue becomes dry and tremulous. The right hypochondriac and epigastric regions are painful and tender. The liver, at first tender and natural in size, or even larger than natural, decreases daily in dimensions, so that at last percussion may give no liver-dullness at all—the softened condition of the liver allowing it to become folded on itself, and the intestines rising up to take its place. With the decrease of the liver, the spleen increases in size. A hæmorrhagic diathesis likewise sets in, as shown by petechiæ on the skin, epistaxis, hæmatemesis, and melæna. The temperature is commonly low, until just before death.

DIAGNOSIS.—The prodromal stage cannot be distinguished from catarrhal jaundice. When the graver symptoms develop the possibility of phosphorus-poisoning must be considered. In the latter disease, the history, the early onset and severe symptoms of gastric irritation, the persistence of the enlarged liver, and the continued excretion of a fair quantity of urea are the points which will best ensure its recognition. Slight disturbances of temperature are not sufficiently characteristic to be of any diagnostic importance.

PROGNOSIS.—The prognosis is extremely bad; probably no cases recover.

TREATMENT.—The treatment must be conducted upon general principles. Intestinal antiseptics, e.g. salol, salicylate of bismuth, β -naphthol, have been recommended. The diet should be limited to milk, diluted, if preferred, with soda-water.

H. MONTAGUE MURRAY.

LIVER, Amyloid Disease of.—**SYNON.**: Albuminoid or Waxy Liver; Lardaceous Liver; Fr.

Dégénérescence Amyloïde du Foie; Ger. *Amyloïde Entartung der Leber*.

ÆTIOLOGY.—The ætiology of amyloid disease of the liver is the same as that of amyloid disease elsewhere. *See* AMYLOID DISEASE.

ANATOMICAL CHARACTERS.—The liver has its normal shape; is more or less enlarged, sometimes to such an extent as to fill the greater part of the abdominal cavity; it has a clean sharp edge, and is firm, resistant, and inelastic, with a smooth glistening surface. The organ cuts like bacon, hence the name 'lardaceous.' The cut surface is a translucent grey, like gelatine or boiled sago, or, in advanced cases, a peculiar subdued red, like that of raw ham; but sometimes it is yellowish or speckled, the liver being anæmic and often fatty also. From the incised veins a little pale blood usually oozes. The characteristic staining-reactions are described elsewhere (*see* AMYLOID DISEASE). The structures invaded by the new material have, in a section examined microscopically, a lustrous, transparent, and somewhat swollen appearance. When the entire lobule is affected, the aspect is homogeneous. The appearance of an amyloid liver may be modified by the co-existence of fatty change, or cirrhosis, or syphilitic disease. The spleen is generally, the kidneys not infrequently, and the intestine and other structures sometimes implicated.

SYMPTOMS.—Palpation, in marked cases of amyloid disease of the liver, will readily detect a large hard resistant tumour, having the normal outlines of this organ; the smoothness of its surface; and the extent to which it encroaches upon the abdominal cavity. Pressure does not elicit any tenderness, nor is there usually any pain; at most, in advanced cases, there is only a sense of tension and fulness, as in other hepatic enlargements. The painless nature of the tumour is distinctive. The disease does not interfere with the portal circulation, and does not therefore directly cause ascites. When this occurs, it is the result of general cachexia, induced by the constitutional malady, and perhaps by associated renal complication. The dropsy generally affects the legs in the first instance, and afterwards the serous cavities, and is not a prominent symptom unless the kidneys are implicated (*see* KIDNEY, Amyloid Disease of). There is no jaundice; or if this occur—a rare event—it is from pressure on the bile-duct externally by enlarged lymphatic glands. The evacuations are, however, frequently of a pale yellow, and at times of a clayey, colour, which may be accounted for by the extensive impairment of secreting structure, and the consequent secretion of a poor colourless bile. Vomiting, without other indications of gastric derangement, and diarrhœa, are symptoms not uncommon in advanced cases, and are no doubt due to the implication in the disease of the vessels and villi of the stomach and intestines.

DIAGNOSIS.—The peculiar features of the enlargement, its painless character, the concurrence of the usual ætiological factors, especially if the spleen and kidneys be involved, will distinguish an amyloid liver from other kinds of hepatic enlargement. If there be associated cirrhosis or syphilitic disease, the diagnosis will be difficult.

PROGNOSIS AND DURATION.—The disease may run on for months or even years. It may disappear if the process that caused it can be arrested, as is sometimes the case with chronic suppuration. But it generally proves fatal, either by intercurrent

affections, or by anæmia, general dropsy, and, exhaustion, such result being more rapidly determined when the kidneys are involved.

TREATMENT.—Surgical measures, directed towards the closing of sinuses, or the stoppage of any discharge that may be present, are of the first importance. But there are many cases—in advanced phthisis, for example, where the position of the disease is a bar to such treatment, or in syphilis—where the only treatment that can avail must be directed especially to the associated cachexia. Whether this be syphilitic or tubercular, the preparations of iodine are indicated: the iodide of potassium, the tincture of iodine, or, where the anæmia is marked, iodine in combination with iron. The syrup of iodide of iron in drachm-doses, three times a day, has proved useful, if not in reducing the tumour, at least in improving the general condition of the patient. The iodine mineral springs, as Woodhall Spa, Kreuznach, Adelheidsquelle, &c., are indicated. The baths of Aix-la-Chapelle, Ems, and Weilbach have each had their supporters in the treatment of this malady. Chloride of ammonium, in ten to twenty grain doses, three times a day, continued for some time, has been found to be efficacious in reducing large hard livers. The general therapeutical indications are pure air, plain nourishing diet, and adequate protection of the skin by warm clothing and other measures.

JAMES F. GOODHART.

LIVER, Atrophy of, Chronic.—A small liver is seen in many wasting diseases, and in old age. The liver shrinks, becoming tougher in consistence, but rarely granular on the surface. The cut surface is dark red or pale brown; the acini are either invisible, or else smaller than natural. The increased toughness is due to the atrophy of the liver-cells, and the resulting condensation of the connective-tissue of the organ.

LIVER, Cirrhosis of.—**SYNON.**: Interstitial Hepatitis; Fr. *Cirrhose du Foie*; Ger. *Chronische interstielle Leberentzündung*.

The term 'cirrhosis' was originally employed by Laennec, who considered that the liver was full of a yellow (*κίττός*) new growth.

Under this heading two forms of cirrhosis of the liver must be dealt with: (i.) *Common or portal cirrhosis* and (ii.) *Biliary cirrhosis*. A third variety, *Interlobular cirrhosis*, is described under syphilitic disease of the liver.

Portal Cirrhosis.—**SYNON.**: Common, atrophic, or multilobular cirrhosis; Hobnailed liver; Chronic interstitial hepatitis; Gin-drinker's liver.

DEFINITION.—A chronic disease, characterised by dyspepsia, hæmatemesis, ascites, little or no jaundice, debility, and a semicomatose state before death. The morbid changes are a multilobular fibrosis of the liver and degeneration of the liver-cells.

ÆTIOLOGY.—The morbid process is set up by poisons reaching the liver, chiefly, though not entirely, by the channel of the portal vein. *Chronic alcoholism* is such a common feature in the history of patients with cirrhosis that it might at first sight appear that the direct action of alcohol on the liver produced cirrhosis. Experiments on animals, however, while proving that alcohol is a protoplasmic poison and induces fatty degeneration in the liver-cells, do not support the view that, *per se*, it leads

to hepatic fibrosis. The action of alcohol is probably indirect. Gastro-intestinal catarrh is the first step; this gives rise to the formation of poisons in the alimentary tract, which, when carried to the liver, cause cirrhosis. *Dyspeptic* cirrhosis has been described and referred to the action of fatty acids, such as acetic, butyric, valeric, and may be set up by stimulating articles of diet, such as spices, curries, and sauces. The association of alcoholism with cirrhosis has been thought, but without any convincing evidence, to depend on bodies other than alcohol contained in wine, whisky, &c., such as sulphate of potassium (Lancereux) and amyl-alcohol.

In some instances cirrhosis may be due to the effects of poisons generated in the course of the *specific fevers*—scarlet fever, measles, typhoid, &c. *Malaria* has been assigned as a cause, but here the causal relationship is very doubtful. It is probable that micro-organisms absorbed from the bowel may give rise to cirrhosis (Adami), but convincing proof is not yet forthcoming.

The poison of syphilis, especially in young children, may be looked upon as so preparing the soil that the factors ordinarily inducing cirrhosis work at a great advantage, and a 'parasymphilitic' cirrhosis results. It has recently been suggested that poisons manufactured in the spleen in severe splenic anæmia (Banti's disease) and other infections may, when carried to the liver, cause cirrhosis.

Sex and age.—It is commoner in men than in women, in the proportion of $5\frac{1}{2}$ to 2. The average age at death is about forty-eight years; it may, however, occur in young children.

MORBID ANATOMY.—The size of the liver is very variable: it may be smaller than natural, and justify the term 'atrophic'; in such instances it may only weigh thirty ounces. On the other hand it may be enlarged to twice its normal size. Sometimes, but by no means always, large cirrhotic livers show extensive fatty change (*fatty cirrhosis*). A large (non-fatty) cirrhotic liver is often associated with latency of symptoms. The larger cirrhotic livers are less knobby or hobnailed than the smaller ones. In some instances the 'hobnails' show hyperplasia, and are so exaggerated that the condition is called *nodular cirrhosis* or *cirrhosis with multiple adenoma*. A further change in the 'adenomata' may result in the development of carcinoma—primary carcinoma with cirrhosis. This is a very rare event. The surface of the cirrhotic liver is irregular, granular, or hobnailed; the capsule is somewhat thickened and opaque, and may be united to the diaphragm by adhesions which are markedly vascular. The 'hobnails' are lobules of liver-cells squeezed into prominence by the fibrous tissue contracting around them, and are often yellow from fatty change and bile-staining, thus justifying Laennec's term 'cirrhosis.'

As a rule the liver is uniformly affected, but sometimes the left lobe is in a more advanced state than the rest. On section the organ is much firmer than natural, and is seen to be divided up by grey, slightly gelatinous-looking strands of fibrous tissue into small compartments of varying size. Microscopically fibrous tissue in various stages of development and containing elastic fibres spreads out from the portal canals to form meshes of different sizes, and encloses a varying number of hepatic lobules. The condition is therefore called multilobular cirrhosis, in contrast to unilobular cirrhosis

(*vide* Biliary Cirrhosis), where the tendency is for each lobule to be separated from its fellows by a distinct fibrous sheath. In the fibrous tissue small round cells are present when the process is advancing. Columns of deeply staining small cubical cells—the so-called new bile-ducts—are frequently seen in the fibrous tissue. Their nature has given rise to a good deal of discussion. The liver-cells are atrophied, and frequently show fatty change; pigment-granules are sometimes present, especially in malarial cases. Compensatory hyperplasia of the liver-cells may occur, and probably plays an important part in nodular cirrhosis and in the formation of the so-called new bile-ducts.

The gall-bladder and bile-ducts are usually healthy, but small bilirubin-calcium calculi are not infrequent in the ducts. The branches of the portal vein are compressed inside the liver, while its trunk usually shows some slight thickening. An important compensatory mechanism, by which the blood of the portal vein can get into the inferior and superior venæ cavæ, is provided by dilatation of the normal anastomoses between the portal vein and the general systemic veins. The more important of these anastomoses are (a) the communications between the œsophageal and the gastric veins; (b) between the superior hæmorrhoidal and the other hæmorrhoidal veins; (c) the veins of Sappey (paromphalic) in the falciform ligament of the liver and the veins of the abdominal wall around the umbilicus; and (d) widespread anastomoses between the veins of the peritoneum, duodenum, colon, and those of the abdominal parietes. The first two of these anastomoses may give rise to œsophageal varices and to hæmorrhoids respectively.

The spleen is enlarged in cirrhosis, not from backward pressure alone but also from a toxic condition of the blood, combined with passive engorgement. The stomach and intestines show signs of chronic catarrh; the heart is flabby, and may present fatty degeneration.

Two important though not necessarily associated lesions are tuberculosis, especially of the lungs, and renal disease.

CLINICAL COURSE AND SYMPTOMS.—The onset is often preceded by long-standing dyspepsia and by symptoms of chronic alcoholism. The face may be muddy and sallow, the venules dilated to form 'stigmata,' and the conjunctivæ slightly icteric; well-marked jaundice is not common. The tension of the pulse is low, the temperature, as a rule, normal, and the tongue furred. At this stage the liver will be found to be enlarged and tender, while the spleen is palpably enlarged. The urine is high-coloured, and is usually free from albumen. The disease may be divided into the early or pre-ascitic stage, and the late or ascitic stage. Hæmatemesis usually occurs a considerable time before ascites develops, and only exceptionally after ascites has made its appearance. It may come on suddenly and without warning, or be preceded by malaise or a debauch. The amount of blood vomited is large, and though it may give rise to severe anæmia, hæmatemesis is rarely fatal. It is followed by melæna. It may be due to ulceration of a varicose œsophageal vein, and may then be repeated—this is the condition found in most of those rare cases where hæmatemesis in cirrhosis is fatal—to gastritis, or to minute erosions or breaches of surface of the gastric mucosa. As a rule, after recovery from the hæmatemesis the patient continues in much the same

state as before for a considerable time, and may even, if fortunate enough to change his habits, regain good health, the disease becoming compensated for or latent.

In most cases, however, ascites develops after a varying interval; its appearance is often preceded, and its onset marked, by a flatulent condition of the abdomen. Since ascites occurs late in the disease, the patient usually is somewhat wasted and has lost strength and vigour. The onset of ascites is usually gradual; its rapid development may be due to thrombosis of the trunk of the portal vein—an occasional complication of cirrhosis. Ascites may interfere with a correct estimate of the size of the liver and spleen, and may be either preceded or followed by œdema of the feet. It is often said that the liver is larger in the early stages, and subsequently contracts and becomes smaller; variations in size undoubtedly occur, but depend more on congestion and its relief than on fibrosis and its subsequent cicatricial contraction. The abdominal wall is stretched, somewhat thin, and may show lineæ albicantes, while dilated veins (*caput Medusæ*) around the umbilicus are usually present. As the ascitic effusion increases the heart is pushed up, an apical or basic systolic murmur being not uncommon; while the thorax is encroached upon so that respiration is interfered with. Under these conditions paracentesis should be performed without delay. In cirrhosis, uncomplicated by chronic peritonitis, paracentesis is rarely required more than once or twice: the ascites may then cease to collect or even pass away; but the patient rapidly fails, becoming drowsy and exhibiting toxic symptoms due to hepatic inadequacy or, in other words, to the liver failing to arrest poisons derived from the alimentary canal (*see* ASCITES). There may be low delirium or semi-coma, and occasionally convulsions. In this stage hæmorrhages into the skin and bleeding from the gums and other mucous membranes may occur; epistaxis is not infrequent. Sometimes death is due to diarrhœa, hæmatemesis, or melæna, but usually it is preceded by increasing weakness and coma.

COMPLICATIONS.—Tuberculosis is frequently associated with cirrhosis; phthisis may indeed sometimes throw the symptoms of cirrhosis completely into the shade. Tubercular peritonitis is another complication that may occur. Owing to diminished resistance, acute infections, such as erysipelas, pericarditis, infective endocarditis, and peritonitis, may supervene; or occasionally an acute infection may attack the liver itself and give rise to the symptoms of icterus gravis. In very rare instances primary carcinoma supervenes in a cirrhotic liver—primary carcinoma with cirrhosis; the symptoms are the same as in cirrhosis.

Thrombosis of the portal vein occurs in a small proportion of cases and shows itself by the rapid development of ascites. Right-sided pleural effusion is not uncommon, and may be due to the spread of inflammation, or possibly infection, from the liver; sometimes the effusion is blood-stained, and is then associated with tuberculosis. Marked cardiac failure may occur and obscure the existence of cirrhosis. Some degree of alcoholic neuritis may also co-exist.

DIAGNOSIS.—The history of alcoholism, hæmatemesis not manifestly due to other causes (*see* p. 620), with splenic and possibly hepatic enlargement, followed by ascites, are the important points in arriving at a diagnosis of cirrhosis. The association of hæmat-

emesis and ascites strongly suggests cirrhosis. The chief conditions from which a differential diagnosis is necessary are syphilitic disease of the liver, malignant disease, and perihepatitis and chronic peritonitis. Signs of syphilis should always be looked for carefully, and it is a good rule to give iodides in cases thought to be cirrhosis, since in gummatous disease of the liver all external signs of syphilis may be wanting. In carcinoma of the liver it may be impossible to be certain until the ascitic fluid is drawn off, and the liver can be carefully examined. In chronic peritonitis and perihepatitis ascites collects again and again after tapping, which it does not always do in cirrhosis; moreover, there may be signs of arterio-sclerosis, granular kidney, or adherent pericardium, conditions which may be responsible for chronic peritonitis. Hæmatemesis is rare in the conditions, which, by inducing ascites, may be confused with cirrhosis. *See ASCITES.*

PROGNOSIS.—In the early stage and when hæmatemesis has occurred, strict obedience to treatment and the avoidance of alcohol and of stimulating diet may be followed by long latency or even apparent cure of the disease. Much therefore depends on the patient's power of will; while his state of nutrition is of considerable prognostic importance. When ascites has developed the outlook is extremely grave, and most cases die within a few months after being tapped once or twice. Many of the reported cures in cases at this stage are probably examples of syphilitic disease. The maintenance of a free secretion of urine and of a healthy state of the kidneys is in favour of the patient.

TREATMENT.—In the early stage strict abstinence from alcohol is essential, and care should be taken not to give tinctures or spirituous solutions of drugs. The diet should be mild and be free from spicy or stimulating articles of food. Milk, fish, and simple puddings should be taken. The bowels should be kept open and any tendency to dyspepsia checked by careful dieting and appropriate drugs, such as bismuth, bicarbonate of sodium, bitter tonics, dilute acids, &c., according to its character. Exercise and fresh air should be enjoined. Benefit will accrue from a 'course' at Carlsbad, Vichy, or Marienbad, or the Carlsbad waters and 'course' can be taken in this country. Hæmatemesis must be treated by rest, rectal feeding, and opium. Styptics may be given by the mouth, if the hæmatemesis is repeated. Two days after hæmatemesis a saline purge and a blue-pill should be given to clear the blood out of the bowel. Iodide of potassium combined with iodides of sodium and ammonium may with advantage be given both in the early and in the later stages of the disease, on the chance that the disease is really syphilitic, but no drug can remove the fully formed fibrous tissue. The object of treatment is thus to prevent any increase in the morbid change and to allow compensatory changes—hyperplasia of the liver-cells, and the increased anastomoses between the portal vein and the general systemic veins—to develop. It is, therefore, important to keep up the patient's strength and nutrition by tonics.

In the late or ascitic stage free, but not too vigorous, action of the bowels should be promoted by salines and small doses of blue-pill or calomel. Diuretics are useful, especially in the form of the pill containing mercury, squills, and digitalis (Addison's pill); citrate of caffeine may be tried. Copiba is a good diuretic, but care must be taken that it does not upset digestion. Ascites should be tapped when any

embarrassment of respiration, pain, or hæmatemesis occurs, and should not be long postponed; Southey's tubes should be used, and the abdomen be subsequently compressed by a binder or many-tailed bandage. Continued or permanent drainage has not proved successful. The surgical treatment of promoting vascular adhesions between the liver and the abdominal walls and so increasing the compensatory collateral circulation has been employed of late years with some success.

In the ascitic stage a milk-diet must be adhered to; it has the advantages of minimising fermentation and acting as a diuretic.

When toxic symptoms have developed diuretics and purgatives should be continued; hæmorrhages should be met by chloride of calcium, and cardiac failure counteracted by hypodermic injections of strychnine. Considerable benefit follows intravenous transfusion. The writer has on several occasions seen a semi-comatose patient restored to consciousness for some weeks by this means (*see SALINE SOLUTION, INFUSION OF*). When in the last stage of weakness alcoholic stimulants are often given; gin is probably the least harmful, but strychnine hypodermically should be given a trial first.

Biliary Cirrhosis.—This condition will be dealt with under the two heads of (1) Hypertrophic Biliary Cirrhosis; (2) Obstructive Biliary Cirrhosis.

1. Hypertrophic Biliary Cirrhosis.—**SYNON.**: Hypertrophic cirrhosis with chronic jaundice; Hanot's disease.

DEFINITION.—A disease characterised by chronic jaundice, attacks of fever, enlargement of the liver and spleen, and usually by its occurrence in young persons. There is no gross obstruction of the large bile-ducts. Histologically the cirrhosis is more unilobular than in common or portal cirrhosis.

NATURE OF THE DISEASE.—There are different types of this disease, and transitional forms between it and portal cirrhosis occur. Moreover portal cirrhosis may become implanted on it in the late stages, and gives rise to a mixed cirrhosis. Discussion has taken place as to whether it starts as an ascending inflammation of the bile-ducts, the infection spreading from the duodenum, or whether it is a descending cholangitis due to a poison brought to the liver by the hepatic artery; the former is the more probable view.

ÆTIOLOGY.—Males between the ages of 20 and 30 are perhaps most often affected, but children are comparatively frequently attacked. A peculiar and very fatal form of biliary cirrhosis in Brahmin infants has been observed in Calcutta. Several members of the same family may manifest the disease and so suggest some common infective agent. Among children the sexes seem to be equally affected.

There is no proof that alcohol, malaria, or syphilis plays any special part in its causation; it has been noted to follow some infectious diseases such as enteric fever (Boisset), and there is reason to believe that the infection may be water-borne (Boix). The presence of fever, leucocytosis, splenic enlargement often preceding the hepatic change, and glandular enlargement, not only in the portal fissure, but sometimes in other parts of the body, make it probable that the change in the liver is the local manifestation of a general infection. A microbic origin, though probable, has not yet been proved.

MORBID ANATOMY.—The liver is uniformly and considerably enlarged and may weigh from 80 ounces to 8 pounds; except for adhesions, the surface is fairly smooth. On section the liver is firm, of a dark-green colour, and granular. The large bile-ducts, the gall-bladder, the portal vein, and the hepatic artery are healthy.

Microscopically, each individual lobule of the liver is seen to be surrounded by delicate connective tissue (*unilobular cirrhosis*); in places the fibrillar connective tissue invades the lobules (*intercellular cirrhosis*).

The connective tissue is much more fibrillar than in portal cirrhosis, but is more intimately related to the liver-cells; it contains elastic fibres, but not to the same degree as in portal cirrhosis.

In most cases where the disease has existed a considerable time there is in addition portal cirrhosis; this is a secondary lesion, and is probably due to poisons manufactured in the spleen reaching the liver by the portal vein.

The small bile-ducts show proliferation and some fibrosis around them, while the bile-capillaries often contain plugs of inspissated bile. The appearance known as new bile-ducts is prominent, but has no special significance, inasmuch as it is seen in common cirrhosis, gumma, and other destructive lesions of the liver. The cells of the liver are much better preserved than in portal cirrhosis: this is correlated with the prolonged course of the disease. The spleen is much enlarged and weighs from 15 to 40 ounces, or even more, sometimes weighing more than the liver. Adhesions around it are frequently met with. The lymphatic glands in the portal fissure are enlarged, pigmented, and oedematous; exceptionally the glands elsewhere, as in the axilla, groin, &c., are also enlarged. The alimentary canal is, as a rule, free from signs of catarrh.

CLINICAL FEATURES.—The onset is gradual with some malaise, but jaundice is probably the first thing noticed; this is permanent, and though it varies from time to time is progressive on the whole. It never becomes so deep as the 'black' jaundice of malignant disease, since, as shown by the presence of bile in the fæces, the obstruction, which is due to cholangitis of the small intrahepatic bile-ducts, is not absolute. The abdomen enlarges from the increase in size of the spleen and liver. The spleen may be found to be enlarged before the liver, and is much bigger than in portal cirrhosis. It is more prone to excessive enlargement in young children, probably from the fact that the capsule is more distensible than in later life. It may be larger than the liver (*Hypersplenomegalic biliary Cirrhosis*). The liver is very considerably enlarged, smooth and tender. There is no enlargement of the gall-bladder. There is generally an absence of the enlarged subcutaneous veins seen on the abdomen in the common cirrhosis; and ascites either does not occur or only shows itself to a slight degree late in the disease, and is then due to a secondary multilobular cirrhosis. The urine contains bile, and is somewhat diminished in amount. The blood may show leucocytosis. There is a poor state of nutrition, growth is interfered with, and in long-standing cases clubbing of the fingers may occur. The disease is very chronic, and may last seven or more years. From time to time exacerbations in the jaundice together with abdominal pain are met with. Small hæmorrhages and epistaxis are seen,

but copious hæmatemesis is infrequent. Death may be precipitated by acute infections, such as erysipelas, pneumonia, and icterus gravis; in the last event the liver shows the lesions of acute atrophy superimposed on the chronic lesion. Death may occur from increasing weakness, or from toxæmia deepening into coma.

DIAGNOSIS.—The important points in the recognition of the disease are chronic jaundice with bile in the stools, the enlarged and smooth liver, the considerable splenic enlargement, and the absence of ascites and enlarged subcutaneous veins on the abdominal wall. In this way it is distinguished from portal cirrhosis; but it must be admitted that transitional forms occur, and that hypertrophic biliary cirrhosis may towards the end come to resemble portal cirrhosis. It differs from gall-stone obstruction in the absence of typical colic, and in the considerable enlargement of the liver and especially of the spleen. From obstructive jaundice it differs in that bile is present in the fæces. Some, rather unusual, cases of syphilitic disease of the liver resemble it, but outward signs of syphilis should put the practitioner on his guard. Between prolonged cases of infective jaundice and hypertrophic biliary cirrhosis there is very little if any difference except in the degree, duration, and result.

PROGNOSIS.—Though the disease runs a course of years, it is eventually fatal. The average duration is about five years; but during its course the patient is often able to do work.

TREATMENT.—The patient should be placed in the best hygienic conditions, take a light and simple diet, especially milk, and abstain from alcohol. The bowels should be carefully regulated, and auto-intoxication prevented by calomel, salol, or other intestinal antiseptics. A course at Carlsbad, Vichy, or Marienbad should be tried. In short the treatment is much on the same lines as those of portal cirrhosis, to which the reader is referred.

ii. **Obstructive Biliary Cirrhosis** was described by Charcot and Gombault as a fibrosis spreading out from the bile-ducts as a result of obstruction to the outflow of bile. More recent experiments and observations, however, have shown that aseptic biliary obstruction *per se* only gives rise to local necrosis and atrophy of the liver-cells, as in compression of the common bile-duct in cancer of the pancreas; though when infection of the ducts is added to obstruction, as in some cases of gall-stone-obstruction, pericholangitic fibrosis may result.

Cases undoubtedly occur in which biliary obstruction is found to be associated with fibrosis of the liver; but it is undesirable to recognise obstructive biliary cirrhosis as a special morbid entity, inasmuch as (1) the change is not the result of biliary obstruction pure and simple, and (2) the clinical aspect of such cases is usually rather that of obstruction of the common bile-duct than of cirrhosis of the liver.

H. D. ROLLESTON.

LIVER, Cysts of.—Cysts other than hydatid are occasionally met with in the liver, and may reach a large size. They are mostly simple and appear to be of the nature of retention-cysts; but there is a cystic disease of the liver in which small cysts up to half an inch or an inch in diameter are scattered through the liver and likely to be

associated with a similar disease of the kidney, the exact nature of which is at present far from certain. It is of pathological rather than of clinical interest. Dermoid cysts are rare.

LIVER, Enlargements of.—ANATOMICAL RELATIONS.—The normal hepatic dullness extends upwards—in front, to about the sixth rib; laterally, in the mid-axillary region, to the eighth rib; and by the side of the spine, to the eleventh rib. The lower border of the liver corresponds in the nipple line to the lower border of the ribs; and the dullness behind merges into that caused by the right kidney. The left lobe of the liver extends across the epigastrium to the left of the mesial line; the dull sound caused by its upper border merging in that produced by the heart. The upper part of the convexity of the liver rises to a little more than an inch above the sixth rib, the lung dipping down in front, and giving rise to a modified percussion-sound; but for practical clinical investigation it is better to take the line of absolute dullness. The extent of the normal hepatic dullness from above downwards in the right mammary line is nearly four inches, and at the side about four inches and a half. In the middle line in front it extends from the base of the ensiform cartilage to about two fingers' breadth below its point. It should be remembered that the limits of the liver present, compatibly with health, considerable variation; that the organ is relatively larger in early than in adult life; that it is depressed in inspiration, and ascends in expiration; that it is somewhat lower down in the erect than in the recumbent position; and that there is temporary distension during digestion. See PHYSICAL EXAMINATION, *Plate*.

DIAGNOSIS.—There are various sources of fallacy which may lead to an erroneous conclusion as to the size of the liver. Thus, an intestine distended with flatus may get in front of the anterior border of the organ, and lead to the supposition that there is contraction, when the contrary is the case. When there is ascites to any extent, it is difficult to make out the boundaries of the liver. In this case, however, by placing the patient on the left side, so as to let the fluid gravitate in this direction, a diagnosis may often be effected; also, by suddenly pressing the finger down below the ribs, and thus displacing the fluid, one may sometimes detect the enlarged organ. A rigid right rectus muscle is liable to be taken for a tumour; to obviate this source of fallacy the patient should lie on his back with his thighs drawn up, and his attention should be diverted by conversation while the examination is being made. Sources of fallacy may exist in the liver itself, as in malformations or malpositions of the organ; or they may be outside it, either in the abdomen or chest. Malignant disease of the stomach, omentum, or pancreas; a kidney greatly enlarged or unusually movable; or fecal accumulations in the colon, may be mistaken for hepatic enlargement. The following considerations will assist in arriving at a correct diagnosis—(a) enlargements of the liver, however much they may extend beyond, generally occupy the normal site of the organ, and however irregular the surface, the usual outline may be traced; (b) such enlargements usually follow the movements of the diaphragm in full respiration. Effusion into the right pleura may be mistaken for enlarged liver, especially as this organ may be depressed by it, and so appear to extend beyond

its limits in the downward as well as in the upward direction. In pleuritic effusion, however, the dullness on percussion will vary with the position of the patient, and the upper line of dullness will in effusion be straight, or possibly a little convex downwards—in hepatic enlargement or subdiaphragmatic abscess, convex upwards. Pleuritic effusion and hepatic enlargement may, however, co-exist. Pneumothorax, emphysema of the right lung, thoracic tumours, and even extreme pericardial effusion, may depress the liver, and affect the diagnosis. See SUBDIAPHRAGMATIC ABSCESS; and ENTEROPTOSIS.

The principal enlargements of the liver are associated with the following diseases of the organ: Hyperemia or congestion; obstruction of the bile-ducts; abscess; hydatid disease; fatty infiltration; hypertrophic cirrhosis; amyloid disease; malignant growths; syphilitic disease; leucocythæmia; actinomycosis; and cystic disease. These morbid conditions of the liver will be found described under the appropriate headings. Some might be disposed to treat of hypertrophy of the liver as an enlargement of the organ, but it hardly comes within the range of practical medicine, for it but rarely occurs as a complementary restitution of new tissue in the left lobe in response to destruction of large tracts of liver-substance in the right lobe.

JAMES F. GOODHART.

LIVER, Fatty Disease of.—DEFINITION.—A disease attended by painless enlargement and diminished consistence of the liver; due to the presence of a large quantity of fat or oil in the secreting structure; and occurring in connection with phthisis and other wasting diseases, or in persons of luxurious and indolent habits, in whom there is usually an abundant development of fat in the tissues and other organs.

ÆTIOLOGY.—Fatty liver may combine *fatty degeneration* and *fatty accumulation*. Fatty degeneration is met with in association with other hepatic diseases, as acute atrophy, amyloid disease, cancer, and phosphorus-poisoning. It is with fatty infiltration that we are here more particularly concerned. The fat may come either from within or from without the body. The former case is illustrated when the greater part of the fat of the tissues and organs is absorbed, as in the emaciation of advanced phthisis. A fatty liver exists in about one third of the cases of this disease, and is met with much more frequently in females than in males. Fatty infiltration of the liver also occurs in connection with other wasting diseases, and is not infrequent in patients who have been long bedridden. When fat is introduced from without, the affection of the liver is associated with development of fat in other organs and in the tissues generally. Persons thus affected are usually given to undue indulgence in eating and drinking: to eating not only too much food, but food rich in oil and fat, and drinking beer, or other alcoholic beverages, to excess. Want of exercise of mind and body, a heated atmosphere, and luxurious habits, materially assist in determining the affection. In illustration of this cause may be adduced the oft-cited experiments of Magendie, who induced very fatty livers in dogs by feeding them exclusively on butter; and also the production of the *foie gras* in geese, by penning them up in a heated atmosphere and cramming them.

ANATOMICAL CHARACTERS.—In fatty disease the liver is more or less enlarged, but seldom to any great extent; the surface is smooth; the borders are rounded; the substance pits on pressure; and the organ is either of pale yellow or drab colour, or, when partially affected, has a mottled appearance. A portion placed in water floats, showing a diminished specific gravity. On cutting into the organ the knife is greased; and a greasy stain is imparted to blotting-paper applied to the cut surface. Under the microscope in slighter grades, fat-granules and globules are seen to be limited to the outer zone of the lobules in the vicinity of the portal vessels; but in advanced cases every cell will be found to be filled either with separate globules, or with a single large drop of fat. In less extensive infiltration the liver may show a mottled surface, the fat being collected in the outer or portal zone, sometimes in the intermediate or arterial zone, the area of the hepatic veins being free. Fat in limited quantity is always present in the human liver, so that the term 'fatty' can only be applied when it is in excess.

SYMPTOMS.—In the lesser grades of fatty liver there are no distinctive symptoms, either objective or subjective. When the affection is more pronounced, percussion will indicate more or less enlargement, usually in the downward direction; and palpation may detect a rounded border and diminished consistence, and will, at any rate, determine that the organ is not unduly hard, has no irregularity of surface, and does not differ materially in shape from the healthy liver. There is seldom, if ever, any pain—at most, in marked cases, a sense of tension and of uneasiness on lying on the left side. Jaundice is a rare event; and ascites and enlargement of the spleen cannot be classed as symptoms of the disease. In cases of fatty infiltration, dependent on luxurious habits, as regards diet, &c., there is usually more or less development of fat in other organs, as well as in the omentum and subcutaneous cellular tissue. In cases where the liver is much enlarged, and there is much abdominal fat, the upward pressure may interfere with the action of the diaphragm, and cause, especially after meals, embarrassment of breathing. Advanced cases may be associated with irregularity, generally sluggishness, of the bowels; more or less dyspepsia; and loss of appetite; though these symptoms are not characteristic of the condition.

DIAGNOSIS.—The enlargement of the liver, with preservation of its normal shape, without hardness or irregularity; the absence of pain, jaundice, ascites, or enlargement of the spleen; and its association either with the emaciation of phthisis or other wasting diseases, or with the habits of the gourmand and general development of fat in the body, will usually enable us to distinguish fatty from other hepatic diseases.

PROGNOSIS.—The prognosis of fatty disease of the liver is affected by the associated condition of the patient, and will, of course, be unfavourable in phthisis.

TREATMENT.—The general therapeutical indications in fatty liver resulting from luxurious habits of living, point to reform in the direction of diet, air, and exercise. Rich, oily, and fatty articles of food are to be avoided; while sugar and starch should only be taken in small quantities. Beer, in all forms, is objectionable, and so also is every other form of alcohol, except, perhaps, small quantities of

light Bordeaux with meals. Exercise, either on foot or horseback, should be had recourse to daily, but must be regulated according to the soundness of the heart and circulation. Free exposure to pure air, and avoidance of heated rooms, are desirable. The functions of the skin must be promoted by adequate clothing, and by the use of the bath, or by sponging with soap and warm water. The bowels must be attended to, and dyspepsia met by antacids and vegetable bitters. The Carlsbad waters—the warm Sprudel especially—are indicated, being supposed to act upon the redundant fat.

JAMES F. GOODHART.

LIVER, Functional Disorders of.—**DESCRIPTION.**—The liver being the largest gland in the body has a number of extremely important functions connected with the processes of assimilation, nutrition, and metabolism.

The satisfactory discharge of these functions may be impeded or interfered with by a number of different causes and with very various results. A condition of hepatic inadequacy or insufficiency, usually partial and not manifesting itself equally on all the functional activities of the organ, is thus of frequent occurrence. The conception of functional disease of the liver implies (1) that there is no structural change in the organ, and (2) that there is no cause for the disturbance of function except in an inherent want of energy and power in the organ, in other words, that the functional disturbance is primary in the liver and not secondary to morbid processes elsewhere.

As far as our knowledge goes at present there is little proof that primary functional disease, as above indicated, forms a definite morbid entity. It is true that a multitude of symptoms and diseases have in the past been referred to this cause with the result that the lay mind has become imbued with and attracted by the vague conception of functional disorders of the liver; it is undoubtedly true that in practice the vast majority of cases formerly so described admit of more intelligible explanation. The nature of the essential factor may vary: thus (1) in some instances it is temporary morbid change in the liver, such as congestion, cloudy swelling and parenchymatous degeneration of the liver-cells, or transient inflammation; (2) in many cases the liver suffers from the action of toxic bodies manufactured in the intestines or elsewhere; (3) sometimes there is definite structural change, as, for example, in the early stages of cirrhosis or inflammation of the bile-ducts; (4) while in other instances, conditions either due to general perversion of metabolism, such as lithæmia and gout, or arising elsewhere as gastro-intestinal dyspepsia, have been regarded as the manifestations of a primary hepatic inadequacy.

The consideration of the subject will be facilitated by briefly referring to the following important functions of the liver.

The glycogenic function of the liver may be considered as comprising (a) the storing up, in the form of glycogen, of sugar derived from the alimentary canal, and (b) the formation and supply of sugar to the economy. The liver may fail in stopping sugar brought to it, and alimentary glycosuria will result, or the sugar-forming function may run riot and diabetes mellitus develop. The mechanism by which the glycogenic function of the liver is disturbed is a question of much interest and is discussed elsewhere. See DIABETES MELLITUS.

In the metabolism of *proteids* the liver plays an important rôle in supervising the formation of urea. It has been generally assumed that disturbance of this function of the liver results in the production of uric acid at the expense of urea; Murchison indeed based his well-known description of lithæmia (*see URIC-ACID DIATHESIS*) on the supposition that from inherent defect in the liver its functions are disturbed by insufficient causes, and that as a consequence uric acid was poured out in larger quantities into the circulation. That disturbance of hepatic function may play some part in excessive production of uric acid is very probable; but it must be remembered that uric acid may be manufactured elsewhere in the body from nuclein, and possibly also in the kidney. Uricæmia should therefore be regarded as the outcome of a general perversion of proteid metabolism, and not as solely due to disordered hepatic activity. Further, disturbance of the proteid metabolism in the liver is in many instances so manifestly due to structural changes, or to morbid processes, such as dyspepsia and auto-intoxications elsewhere, that it is unsafe to assume a primary disturbance of this function as a common event.

The secretion of bile by the liver was formerly thought to be diminished by a 'torpid' state of the organ in the condition known as *biliousness*. Diminution of the flow of bile into the intestine depends in such cases on catarrhal swelling of the mucous membrane of the bile-ducts. In some instances there may be an incipient catarrhal jaundice from the spread of inflammation from the duodenum to the common bile-duct; while in other cases there is probably catarrh of the small intra-hepatic ducts, set up by irritating and toxic bodies absorbed from the intestinal tract, and often associated with congestion of the liver. It is quite in accord with this explanation that the most satisfactory treatment for this disorder is directed to the intestine, such as Blue-Pill and Mistura Sennæ Composita, and not to stimulation of the liver. *See GALL-BLADDER and BILE-DUCTS; and JAUNDICE.*

By its *antitoxic function* the liver arrests poisons reaching it from the alimentary canal, and prevents their passage into the general circulation. In doing so it may suffer damage, as is seen in an extreme degree in phosphorus-poisoning; and as a result this antitoxic or protective function fails and poisons escape into the blood. Many of the symptoms popularly ascribed to 'torpid liver,' such as headache, drowsiness, irritability and depression, *muscæ volitantes*, and bitter taste in the mouth, are due to the flooding of the circulation with toxic bodies. In well-marked structural change in the liver, as in acute atrophy and in the later stages of cirrhosis, the failure of the antitoxic function of the liver results in extreme hepatic toxæmia or cholemia, which has many resemblances to uræmia. *See JAUNDICE.*

The foregoing remarks have shown that functional disorders of the liver are practically either manifestations of definite structural change in the liver and bile-ducts or secondary to morbid processes elsewhere.

The symptoms which have, many of them, been already mentioned in the sections on the functions of the liver may now be briefly summarised as follows: Distaste for food, dyspepsia, and flatulence are due to gastro-intestinal disturbance, set up by poisonous or unsuitable food. The icteric tint of

the conjunctivæ, the muddy complexion, and the diminished quantity of bile in the stools are accounted for by slight catarrhal obstruction to the outflow of bile from the liver. Piles, the feeling of weight in the right hypochondrium, and the disordered action of the bowels are due to congestion of the liver, brought about by the advent of food-products either poisonous in quality or excessive in quantity. This state of hepatic congestion is readily set up in patients who have suffered from malarial fevers in hot climates, such as India. Headache, giddiness, irritability of temper, malaise, other nervous symptoms, and the bitter taste in the mouth are due to poisons absorbed from the alimentary tract getting into the general circulation from failure of the antitoxic function of the liver. *See BILE, Disorders of.*

The treatment of secondary functional disturbance is to discover and treat the primary cause. Often it is to be found in the alimentary canal, and can be removed by blue-pill and senna-draught. Mercury drives out the bile from the gall-bladder and ducts, and by sluicing out the common bile-duct will have a beneficial effect on catarrh of that duct. Purgation removes the products of fermentation and prevents auto-intoxication, while at the same time it reduces the hepatic congestion.

Plenty of water should be taken, so as to stimulate the action of the kidneys, while a milk-diet free from irritating or stimulating ingredients should be prescribed. Alcohol should be rigidly tabooed while the symptoms last, and only taken sparingly in the intervals. The symptoms due to congestion, early cirrhosis, &c., must be treated on the lines laid down elsewhere. After the symptoms have subsided fairly active exercise, plenty of fresh air, and a carefully regulated diet should be enjoined. As pointed out above, the rational treatment includes that of the primary cause. *See DIGESTION; STOMACH; and the other articles on the LIVER.*

H. D. ROLLESTON.

LIVER, Gangrene of.—*See LIVER, Abscess of; and Inflammation, Acute, of.*

LIVER, Hydatid Disease of.—**ANATOMICAL CHARACTERS.**—The liver is the organ most frequently affected with hydatid disease. There is usually but one cyst, but there may be two, three, or more; and the size of the cyst may vary from that of a pea to that of a child's head. The cysts may exist in either lobe of the liver, but they are more frequent in the right; and they may be attached to the upper or under surface, or project from the border, or lie buried in the substance of the gland. This is more or less modified in form, and increased in size, according to the magnitude and site of the cyst. When the cyst is small and deep-seated, there will be no appreciable change in the liver, and the disease may be latent for years. When, however, the cyst is very large, it, with the liver, constitutes a tumour, which may encroach upon the thorax, and also fill a great part of the abdomen. Pressure of the cyst may induce atrophy of a portion of the liver, but, at times, hypertrophy is the result. The bile-ducts have occasionally been found to be obliterated, or a communication to have been effected between them and the cysts. When at the surface of the organ, the cysts as they enlarge may induce inflammation and thickening of the peritoneum, and adhesion to neighbouring structures.

SYMPTOMS.—A hydatid cyst, when sufficiently large and near the surface, generally exhibits itself as a tumour of variable size, situated either in the right hypochondrium or in the epigastric region; evenly globular in its early stages; firm, resisting, yet elastic, and, at times, with a sensation of fluctuation. Briançon and Piorry noticed a vibration or trembling—*hydatid fremitus*—which is sometimes felt when the surface is compressed gently by three fingers of the left hand, and sharp percussion made with the right hand over the middle finger. If the tumour is situated behind the liver, it will, as it develops, push this organ forwards, flatten it, and increase the area of dullness. The tumour may last for a considerable time, and go on increasing to some extent, and yet the patient may remain free from constitutional disturbance, perform all his functions well, and keep in good condition as regards flesh and strength. When, however, it has attained a very large size, it will give rise to various symptoms—to a feeling of tightness and distension; if it press upwards, to embarrassed breathing, cough, possibly more or less dullness, with diminished respiration, at the base of the right lung, and palpitation; if upon the abdominal viscera, to interference with their functions. Pain is not generally present, but in some cases there is a gnawing pain, either at the epigastrium or extending forwards from the lumbar region. (Edema of the lower extremities may occur when the tumour presses upon the inferior vena cava; or ascites may result from a similar effect on the portal vein.

DIAGNOSIS.—Hydatid tumour of the liver is not always easily diagnosed; but the characteristic features already noticed, and the maintenance (in many cases up to an advanced stage) of a good state of health, will generally point to its nature. Abscess of the liver will be distinguished by local and remote pain; rapidity of onset; the frequent antecedence or co-existence of dysentery; and severe constitutional symptoms, such as hectic fever, rigors, &c. It must, however, be remembered that hydatid cysts are liable to become inflamed and to suppurate, when the diagnosis will not be so readily made; but even so, the suppuration of a hydatid cyst is less likely to be accompanied by the acute paroxysmal fever so characteristic, if present, of abscess of the liver. Cancer of the liver will generally be marked by irregularity of surface, and often a peculiar hardness and heaviness; the presence of pain; the cachectic aspect; loss of flesh; and the rapidity of progress. Aneurysm of the abdominal aorta may form an epigastric tumour, of even spherical shape; but the pulsations, frequently very forcible, coupled probably with a bruit, audible along the course of the vessel before and behind, will determine the diagnosis. The site, the pyriform shape and the uniform size, the greater mobility, and possibly the accompaniment of jaundice, will distinguish from hydatid disease the tumour caused by a distended gall-bladder. Frerichs believed that hydatid disease of the liver is more frequently confounded with localised pleuritic effusion at the base of the chest than with any other affection. He remarks that the same signs—dullness on percussion, absence of vocal thrill, intercostal fluctuation—would be present in both cases. He rests the diagnosis on the fact that the line of dullness would present a curve which would look upwards in the one case, downwards in the other. To this sign, of uncertain presence, may be added

that the vocal vibration and resonance, although perhaps somewhat lessened, are not usually damped by pressure from below the diaphragm to the extent that is effected by fluid in the pleura.

TERMINATIONS AND PROGNOSIS.—Hydatid tumour of the liver may last for years, and be compatible with an average state of health; or, at an early or advanced period of its existence, it may terminate in one of the following ways: 1. It may, from its bulk and position, press upon and interfere with the functions of different organs. Pressure on the large venous trunks may induce ascites and dropsy of the lower extremities; pressure upon the stomach and intestinal canal may obstruct functions connected with the assimilation of food, and induce failure of flesh and strength, and ultimately death from exhaustion. 2. The tumour may contract adhesions with the diaphragm; ulcerative action through this may be set up, and either (a) discharge of the contents of the sac may take place into the pleura, and fatal pleuritis result; or (b) further adhesions and ulceration may effect communication with the lung, when hæmoptysis or pneumonic symptoms ensue, and the contents of the sac, mixed with blood or the products of inflammation, are expectorated. The disease is sometimes cured by this means. 3. A rare result is adhesion to, and ulceration into, the pericardium, with escape of contents, and rapidly fatal results. 4. Adhesion may be effected with some part of the alimentary canal, and the contents of the sac be discharged by vomiting or by stool. 5. Rupture of the sac may be caused by a blow or otherwise; the contents be discharged into the peritoneum; and fatal peritonitis result. 6. The tumour may contract adhesions with the parietes, point externally, and be opened or effect an opening by natural process, inflammation and suppuration having been previously set up in the sac. 7. Budd and Frerichs notice a possible cure from the obliteration of the sac by the formation within it of a putty-like matter, the combined result of degeneration of the cyst and its contents, and of inflammation outside the parent-cyst. These conditions are often seen *post mortem*, and are frequently associated with calcareous changes in the cyst-wall, as well as with the deposition of brown or orange biliary pigment. So generally is pigment of this kind present in various parts of these cured hydatids, that there is good ground for supposing that the rupture of minute bile-ducts into the cyst or its wall is no uncommon thing; and that, either by killing the parasite or by effecting slow inflammatory changes in the bed of the cyst, it leads to a spontaneous cure in no inconsiderable number of cases. As an illustration, although a rare one, of the extent to which the slow inflammatory changes may proceed under favouring conditions, there is a specimen in the museum of Guy's Hospital where the hydatid is surrounded by, and had no doubt determined, an enormous growth of gummatous material. 8. Communication may be effected between a hydatid cyst and one of the larger bile-ducts, and then the result will usually be fatal, although there are one or two cases recorded of recovery. 9. Similar cysts may be formed in other parts or organs of the body. 10. As a possible rare event may be mentioned communication of the sac with the ascending vena cava, escape of the contents into this, transfer of the contents to the right side of the heart, impaction in the pulmonary artery, and fatal asphyxia.

TREATMENT.—So long as hydatid tumours produce no distressing symptoms and do not affect the function of any organs, there is no pressing cause for interference. But as some of the inconvenient or dangerous symptoms mentioned in the last paragraph are likely sooner or later to occur, and as, owing to the improvements in modern surgery, interference with these cysts is now far less dangerous than it used to be, it is generally recommended that they should be treated surgically without much delay. The special forms of inconvenience which would make operation necessary are the size of the cyst and the presence of adhesions to, or mechanical interference with, surrounding parts. Any of these may cause disturbance of the functions of neighbouring viscera or induce ascites from pressure on the portal vein. The symptoms which are indicative of approaching danger are those of acute or chronic suppuration, or an obvious extension of the cyst upwards, rupture into the pleura being an occasional and extremely dangerous complication, and one which, if not actually fatal, is likely to leave a completely collapsed lung and an incurable pneumothorax.

It was formerly recommended that hydatids of the liver should be punctured with a fine trocar and cannula; and the reports of Australian and other surgeons render it certain that a number of cases may be cured in this way. There are, however, certain dangers in connection with this method of treatment which appear to be unavoidable, especially those arising from leakage of the contents of the cyst into the peritoneal cavity. It is also recognised that by no means all the cases can be cured in this way. It is therefore usually recommended in this country that the cyst be drained or removed without recourse to previous tapping. In a case where a cyst of some size impinges on the abdominal wall, the operation consists in making an incision over the most prominent part of the tumour, or, if possible, at a somewhat higher level. The cyst-wall is grasped with volsella and the needle of an aspirator is plunged into it. As the fluid is drawn off the cyst collapses and its walls can be drawn into the wound. At this period the wall may be freely incised, and the daughter-cysts together with the endocyst removed. The cyst-wall is then stitched to the skin of the abdominal wall and a drainage tube inserted. In the case of smaller cysts it may be necessary to perform the operation in two stages: in the first, the tumour is exposed and means are adopted to ensure the presence of adhesions; in the second the cyst is opened and treated as in the case of the larger cyst. Occasionally it is found possible to dissect out the whole cyst; and this is especially the case if the wall has become calcified. Under these circumstances this is the only treatment to pursue, and it usually presents no great difficulties.

Treatment by free incision and drainage is not altogether free from danger. Serious hæmorrhage may occur, but this is rare. The greatest risk is in connection with the possible occurrence of septic changes after the operation. If this should happen when the cyst is large, the patient's life will be in danger. It is therefore of the greatest importance that throughout the treatment the strictest attention should be paid to all the antiseptic arrangements. When operating it is important to recollect that hydatid cysts may project upwards at least as far as the second rib in front; and that cysts, not

necessarily of large size, may be found in the right iliac fossa or touching the spleen in the left hypochondrium.

If it be decided to adopt the method of simple puncture, the least dangerous method is to employ the aspirator, but if this be done it is very important only to exhaust a small quantity of air from the bottle before the needle is inserted, and afterwards to work the pump very slowly, otherwise the daughter-cysts will be sure to be drawn against the eye of the cannula, and the escape of the fluid thereby prevented. Such methods of treatment as the injection of the cyst with some stimulating fluid, or the gradual opening of it by the application of caustics, are now obsolete.

Treatment by medicinal agents administered internally has proved entirely useless.

JAMES F. GOODHART.
R. J. GODLEE.

LIVER. Hyperæmia (Passive) of.—SYNON.: Passive Congestion of the Liver; Nutmeg Liver.

DEFINITION.—Uniform enlargement of the liver, with preservation of its normal shape; caused by over-distension with blood, the result of mechanical obstruction to the return of blood to the heart. It may be attended by a sense of fulness and oppression in the right hypochondriac and epigastric regions, and often by slight jaundice.

Passive congestion is due to interference with the return of blood from the liver through the hepatic vein and inferior vena cava to the heart. Such interference may be due immediately to dilatation of the right heart, with affection of the tricuspid valve; to obstruction to the circulation in the course of the pulmonary artery, caused by different diseases of the lungs; or, farther on, in the line of the circulation, to disease of the mitral or aortic valves. The affections of the lungs which interfere with the pulmonary circulation are either acute, as pneumonia, and then the hepatic hyperemia may pass off with the disease; or they are chronic, as emphysema and fibroid disease, and then the hyperemia will persist. Passive congestion of the liver may result from direct obstruction to the flow of blood by the pressure on the inferior vena cava of aneurysmal or other tumours, or of the cicatricial tissue formed as a result of mediastino-pericarditis. Mere weakness of the heart's action often keeps up a certain amount of passive congestion.

ANATOMICAL CHARACTERS.—A hyperæmic liver is increased in size about equally in all directions; its resistance is also increased; its peritoneal investment appears distended and shining. On making an incision blood oozes out freely, and the cut surface is dark red—either uniformly so, or spotted with intervening lighter spaces. The central vessels of the lobules—the hepatic veins—are engorged; and when persistently so, as in disease of the mitral valve, the cut surface gives the characteristic appearance to which the term *nutmeg liver* has been applied. The dark centres contrast with the pale circumference of the lobules, the light and dark parts being clearly defined, but varying according to the section; the surface gives an appearance which resembles closely that of a cut nutmeg. The central dark spots result from distension of the hepatic veins, and deposition of bile-pigment in the adjacent hepatic cells, which are more or less atrophied by pressure; the lighter spaces correspond to the circumference of the lobules, the light colour
